The solar chromosphere–corona transition region is highly structured, both in space and in time. Intensity observations indicate that the dominant portion of the transition region radiation arises in regions of variable emission. There are, however, two characteristics of the observations that seem to be invariant from region to region and from time to time; the shape of the emission measure curve and the net redshift of spectral

lines. It should be mentioned that the redshift decreases toward the limb of the Sun indicating that motions are primarily vertical. The invariant shape of the emission measure curve and the net redshift are also seen in the observations of several other stars. Most of the numerical models constructed have been designed to explain these observational facts.

An outstanding problem in transition region physics is that the temperature structure one derives from assuming that the dominant term in the energy equation is thermal conduction does not seem to correctly reproduce the observed emission of spectral lines formed at temperatures below, say, 2×10^5 K but instead predicts intensities several orders of magnitude less than is observed. The cause of this discrepancy is the sharp temperature gradient, due the dominance of thermal conduction, and the associated paucity of material in the temperature range which supports emission from a specific ion. Antiochos and Noci have proposed a promising solution to this dilemma by assuming that much of the lower transition region emission stems from regions where the local heating is low enough to ensure low loop apex temperatures, thus reducing the role of thermal conduction and 'stretching' the temperature profile in the loop. On the other hand it has been argued by Athay and Holzer that transition region emission may the result of episodic heating and that the observed transition region intensities may be reproduced by models of loops that cycle between having high and low apex temperatures. The resolution of this issue awaits a better understanding of spicule dynamics and the coronal heating process.

Analysis of spectral line profiles show that transition region lines display a net redshift (redshifts imply motions towards the solar surface). The observed mean redshift is typically 5–10 km s^{-1} for the spectral line C IV λ1548 which is formed near 10^5 K. The amplitude of the shift is reduced for lines formed at lower temperatures and chromospheric lines display little net shift. There are few observations of higher-temperature lines but there is evidence that the net redshift is reduced or disappears in the upper transition region. Models of the net redshifts have invoked selection effects in the radiative or temporal properties of gas flowing up versus down. Athay and Holzer hypothesized that the redshifts were caused by the return of spicular material. Alternately, the observational signatures have been interpreted as siphon flow through coronal loops. McClymont and Craig, and Mariska, showed that asymmetric heating of coronal loops may drive such flow. Both ideas seem compelling; however, the development of both into detailed models has been hampered by the lack of numerical computations or, in the case of siphon flow, by the fact that calculations by Spadero *et al* predict blueshifts rather than the observed redshifts when time-dependent ionization is incorporated into the models. Hansteen has proposed that the net redshifts may be explained as a consequence of nanoflare (episodic) coronal heating: episodic heating in a coronal loop should generate waves, some of which will propagate along the loop and through the transition region. Propagating compressive waves will cause spectral line asymmetries and line shifts in the 'direction' of wave propagation which in this scenario are primarily directed downwards producing redshifts. The further development of this idea awaits two- and three-dimensional simulations as well as theoretical predictions on the nature of episodic energy release in the corona.

As we have seen, transition region emission is fairly sensitive to processes occurring in both the chromosphere and corona and could to used to effectively discriminate between various models of these regions. The availability of observations from the Solar and Heliospheric Observatory (SOHO) instrument Solar Ultraviolet Measurements of Emitted Radiation (SUMER) which feature transition region data of unprecedented temporal, spectral and spatial quality should push transition region modeling into considering full two- and three-dimensional models of the outer solar atmosphere where the details of the interaction between the chromosphere, the transition region and the magnetic field are treated with more seriousness than has been the case until recently.

Transition Region: Explosive Events

Explosive events are frequent, very small bursts that occur throughout the solar transition region. There are something like thirty to forty thousand of these events on the Sun at any time. Each event lasts for roughly a minute so every second there are about 600 new events. Present-day solar telescopes are just able to resolve the largest of these events. The events give an impression of explosion because highly supersonic mass motions (measured as Doppler shifts) are nearly instantaneously produced within a small area. The velocities reach up to 150–200 km s^{-1} during the first few seconds and they last for 1–5 min. The typical size is 1000–4000 km and there is no detectable transverse motion of the event site. Explosive events are most clearly seen in ultraviolet spectral lines formed at temperatures of about 10^5 K. The few measurements of number densities indicate densities of about 5×10^{15} m^{-3}. Their mass and kinetic energy are estimated to be 5×10^5 kg, and 10^{15} J respectively.

A distinguishing feature of explosive events is that they produce large Doppler shifts in emission lines formed at transition region temperatures. Emission lines from plasma at these temperatures are all found in the ultraviolet wavelength range (as explained in the SOLAR TRANSITION REGION). The image in figure 1 shows line profiles of an ultraviolet line from the three times ionized silicon ion, along a long, narrow strip of the Sun. This line, Si IV 1393 Å, is formed at roughly 10^5 K. Three prominent explosive events all with very different but characteristic line profiles can be seen. In the event at the top, the red- and blueshifted emission is slightly offset along the N–S directed spectrometer slit. The event in the middle has a highly asymmetric blueshifted profile (strongly redshifted profiles are also common). It is also typical that the larger, brighter events, such as the lower event in the image, have higher Doppler velocities.

Explosive events have now been observed in many spectral lines. They are most often seen in lines such as C IV 1550 Å, Si IV 1393 Å and O IV 790 Å that are formed at plasma temperatures near 10^5 K. Higher temperature events that show up in lines such as Ne VIII 780 Å formed near 5×10^5 K are about ten times less frequent. Likewise events exhibiting emission in lines from lower temperature ($2–3 \times 10^4$ K), singly ionized species, for example in C II 1335 Å, are also about ten times less frequently seen. The high velocity ultraviolet line shifts that characterize explosive events are usually accompanied by a brightening of the line intensity; however the converse is not true. For example, the brightening of transition region lines associated with x-ray bright points is not usually accompanied by explosive events (see SOLAR CORONA: X-RAY BRIGHT POINTS).

The fact that explosive events are only observed in ultraviolet spectra which must be obtained from space telescopes makes them difficult to study. Their small size and comparatively short lifetime requires high spatial, temporal and spectral resolution. So far only two instruments have had high enough resolution to unambiguously identify explosive events. They were first discovered in spectra from the High Resolution Telescope and Spectrometer (HRTS) of the Naval Research Laboratory during its first rocket flight in 1975. Subsequent rocket flights and a Spacelab 2 mission with this spectrometer enabled a basic understanding of their observational statistics, their relationship with x-ray bright points and the photospheric magnetic field. In 1996 with the launch of SUMER (Solar Ultraviolet Measurements of Emitted Radiation), the high resolution ultraviolet spectrometer on board the spacecraft SOHO (the Solar and Heliospheric Observatory) it became possible to observe the relationship of explosive events to the network structure over periods of several hours.

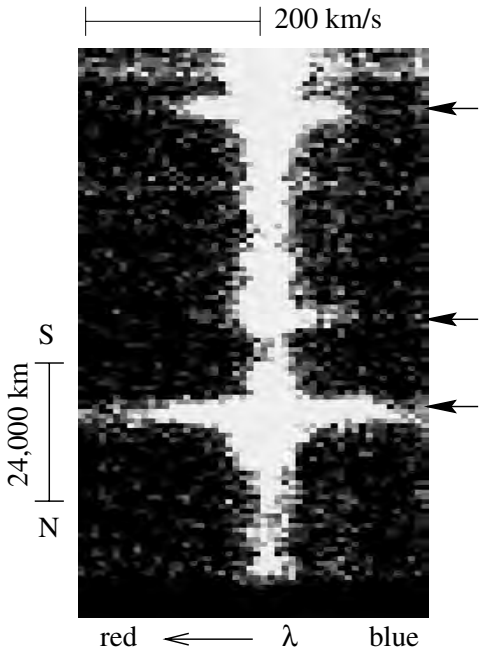

Figure 1. An example of three explosive events in Si IV 1393 Å observed with the long slit ultraviolet spectrometer SUMER on the spacecraft SOHO. The image shows line profiles along the 90 000 km long slit with spatial resolution 800 km, velocity resolution 12 km s^{-1} and integration time 10 s. Blueshifts (decreasing wavelength) are on the right.

The results of one such study are shown in figure 2 where the supergranular network pattern (see CHROMOSPHERE: NETWORK) of bright cell boundaries with dark centers is shown on the left and the evolution of the line profiles at four representative positions on the right. These four positions lie on a bright network lane (A), a dark cell center (C) and faint network lanes (B and D).

This figure illustrates the frequency of explosive events and their relationship to the network structure. Most explosive events and brightenings are in the network lanes and, in particular, close to bright emission regions. There are also one or two faint, low-velocity ($\sim$60 km s^{-1})

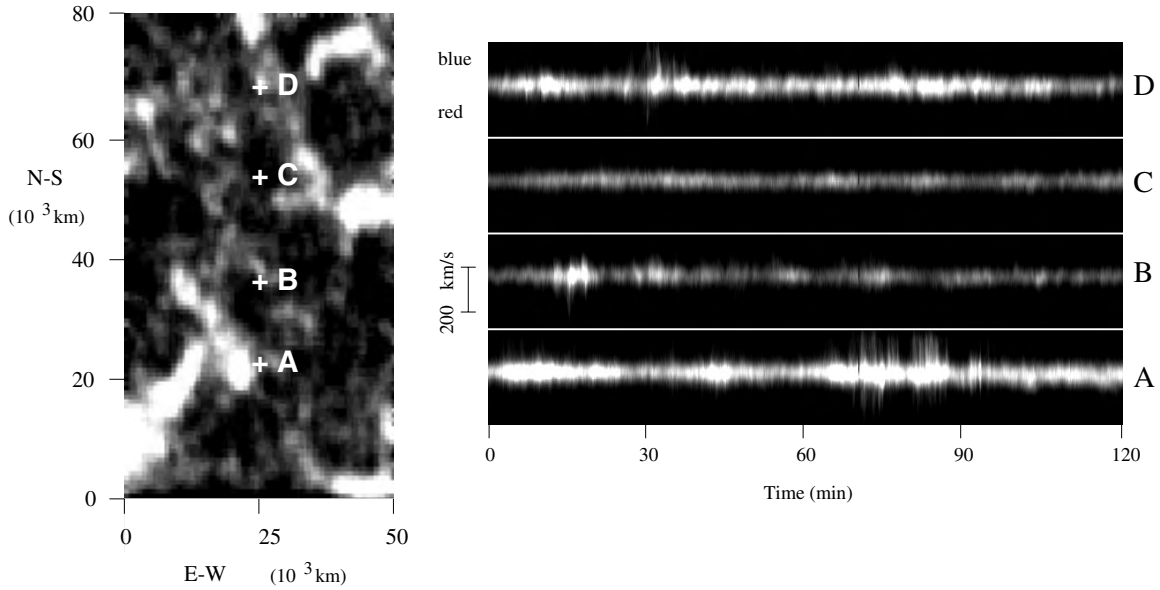

Figure 2. Explosive events and their relationship to the chromospheric network as observed by the spectrometer SUMER. The picture on the left shows the structure of the chromospheric network. The positions chosen to demonstrate typical line profile evolution are marked with white crosses and letters. The time evolutions of the Si IV 1393 Å line profiles at these four positions over a period of two hours are shown in the right-hand frames. In each frame, the profiles range from blueshifts of about 150 km s^{-1} at the top to redshifts of about 150 km s^{-1} at the bottom.

events in the dark cell center. Along the network lanes, the individual events often occur in bursts that can last up to 30 min.

Since their discovery, it has been suggested that the underlying process triggering the events is the conversion of magnetic to kinetic energy by magnetic reconnection. There is also strong observational evidence that the events are related to the structure and evolution of the photospheric magnetic field. As illustrated in figure 2, explosive events occur predominantly along network lanes. This is where weaker magnetic field elements are continually merging and cancelling with stronger network fields. In recent ultraviolet line profile and magnetic field observations, several explosive events were seen simultaneously with evolving magnetic field elements. Figure 3 shows the position of the explosive events in relation to the magnetic field and it can be seen that most events lie on or near magnetic neutral lines (i.e. the boundary between positive and negative field regions). The small burst of events on the left side of the positive field region marked with an arrow, seems to be associated with decreasing photospheric flux. Some explosive events have been seen far from any detectable magnetic fields. These are however always single events, not bursts of events, and it is possible that very small magnetic field elements are involved.

Another clue to the origin of explosive events comes from their spatial flow structure. By making small repetitive scans with a long slit spectrometer it is possible to build up an image of the time evolution of the explosive event flow. Figure 4 illustrates the evolution of the time

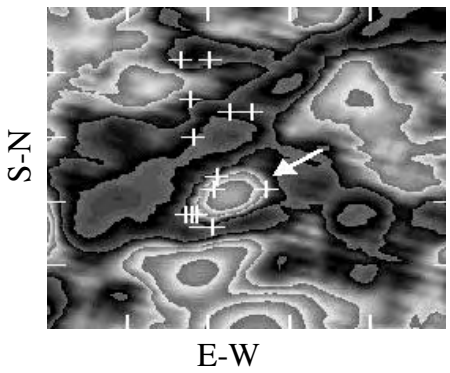

Figure 3. A quiet Sun magnetogram with the position of explosive events marked with white crosses. The brighter (darker) features are positive (negative) polarity magnetic fluxes. The tick interval on the E–W and S–N axes is 3600 km. (Courtesy of J Chae, Big Bear Solar Observatory.)

pattern of observed Doppler shifts. As in figures 1 and 2, this again is a series of Si IV line profiles. One of the most important features illustrated in figure 4 is that the Doppler shifts change from red to blue as the bright central position of the event is scanned in the E–W direction. Closer inspection shows that the width of the event slowly increases in both the E and W directions although the position of brightest emission does not move.

These features show that the word 'explosive' is misleading. An explosion would eject material in all directions and should produce symmetric red- and

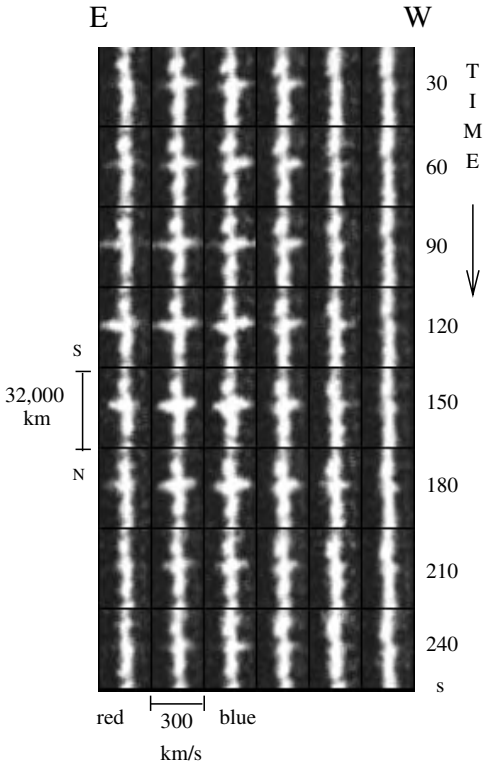

Figure 4. Evolution of Si IV line profiles. Each sub-plot of the figure shows a 32 000 km section of a spectrum along the slit for Doppler velocities from redshifts of 150 km s^{-1} to blueshifts of 150 km s^{-1}. Time increases from top to bottom. Each row shows the profiles along an E–W scan with a step size between subplots of 800 km.

blueshifted profiles. Also material that has moved across the disk furthest from the explosion site would have the lowest line-of-sight velocity. Therefore the high-velocity asymmetric profiles on the east and west edges of the events cannot be explained by an explosion. There are two flow configurations that can produce the pattern observed in figure 4. One is a bi-directional jet and the other is a spinning disk of gas. At present no-one has been able to find an observational means of determining which flow it is.

If the flows are bi-directional jets then the observed pattern of red and blue Doppler shifts could be a confirmation of the Petschek theory of fast reconnection. This theory predicts oppositely directed plasma jets ejected from a small localized site. As described elsewhere (see MAGNETOHYDRODYNAMICS: MAGNETIC RECONNECTION AND TURBULENCE) magnetic energy is converted into plasma thermal and kinetic energy at the jets' source, the diffusion region, and along stationary slow mode magnetoacoustic shocks that form along the jets' boundaries (figure 5). Petschek models reproduce the high-velocity components but they do not account for the bright emission at the center of the line profiles. It is likely that the diffusion region is more complex than the small localized site assumed in the

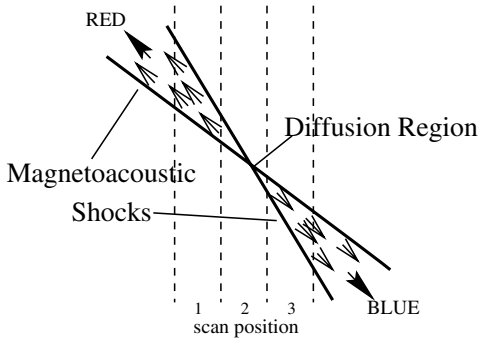

Figure 5. Flow geometry of jets that would reproduce the observed pattern of red and blue Doppler shifts shown in figure 4. In Petschek-like models the reconnection site would be at the centre of the bi-directional jet.

Petschek theory.

Explosive events play a crucial part in the understanding of quiet Sun transition region heating, flows and most probably also the solar corona. The total energy in the observed mass motions of explosive events is insufficient to be important for coronal energy balance but they probably represent the high-energy tail of a spectrum of network events that occur on scales unobservable with currently available techniques.

Transition Region: First Ionization Potential Effect

The first ionization potential (FIP) effect causes a fractionation, i.e. a change of the relative abundances, of elements with a low FIP in the corona and solar wind as compared with the SOLAR PHOTOSPHERE. These elements (specifically Mg, Si and Fe) are becoming enriched somewhere in the solar atmosphere by an average factor of 2–5 relative to the high-FIP elements (specifically oxygen). The process most likely involves separation of atoms and ions across magnetic field lines in a partially ionized gas, and the site can probably be identified with the upper chromosphere or the lower transition region. An understanding of the FIP fractionation effect is important for obtaining element abundances in the Sun from solar wind measurements, and in turn it provides information on the conditions prevalent and the processes operating at the relevant site in the solar atmosphere.

FIP fractionation observations

When we compare the normalized elemental abundances (relative to oxygen) of the SOLAR WIND and of the CORONA (as inferred from the solar energetic particle (SEP) population) with the photospheric abundance ratios, we notice a significant fractionation between the two populations. If this fractionation is plotted as a function of the FIP, a regular pattern emerges. Elements with a low FIP ($\lesssim$10 eV) lie on a plateau which is enhanced by a factor of $\sim$3–5 with respect to elements with a high FIP ($\gtrsim$10 eV). The intermediate elements with an FIP near 10 eV, carbon and sulfur, are also enriched, but by smaller factors. The high-FIP elements again lie on a plateau up to, and including, neon, but helium, the element with the absolute highest FIP, is underabundant by a factor of $\sim$2 relative to the high-FIP elements. This basic FIP pattern is obeyed by the SEP population and, with some exceptions discussed below, by the slow solar wind normally encountered near the ecliptic plane (see figure 1). It was first described for the SEP population by Hovestadt in 1974, and in 1981 Meyer first noted the same effect to hold in the slow, in-ecliptic solar wind.

With the abundances of more elements becoming available, and with the possibility to determine abundances as a function of the solar wind flow type, exceptions from the basic FIP pattern described above have become apparent. The most important one is a reduction of the fractionation factor between low- and high-FIP elements, the FIP bias, in the fast solar wind from CORONAL HOLES (i.e. in high-speed streams) to a factor of $\sim$2 instead of $\sim$3–5 (figure 1). It is interesting to note that carbon, which is slightly enriched relative to oxygen in the slow wind, seems to remain unchanged in fast streams, i.e. its slight enrichment is not reduced proportionally with that of the low-FIP elements. It may therefore be that this element behaves as a (slightly enriched) high-FIP element in the slow, interstream solar wind but as a low-FIP element in fast streams, even though its enrichment factor does not change.

The heavy noble gases, krypton and xenon, do not follow the basic FIP pattern either. Both are high-FIP elements, but both are enriched in the solar wind, by factors of 2 (Kr) or even 4 (Xe). (These abundances were obtained from inclusions in the lunar regolith, which were integrated over millions to billions of years; therefore the values are identified with the slow, in-ecliptic solar wind, and no fast wind value can be given.) This enrichment may be understood to be a consequence of their high mass (see next section), and of their relatively short ionization time as compared with other high-FIP elements. It has been argued that the first ionization time (FIT) may therefore be the better ordering parameter than the FIP. Ionization times are calculated by folding the solar UV and EUV spectrum with the ionization cross sections. Indeed, when the abundance data are represented versus FIT, a simple new fractionation pattern is easily visible: low-FIT ($\lesssim$10 s) elements again lie on a plateau, but the fractionation factor of high-FIT elements now is roughly a power law in FIT with an exponent of $\simeq -0.5$, and all high-FIP elements, including Kr, Xe and He, follow this pattern (see figure 2). However, the FIT is not a fundamental atomic parameter, and it is highly variable as a consequence of the UV and EUV variability with the solar activity cycle. Therefore, the name of the 'FIP' effect should nevertheless be preferred.

Recently, the FIP effect has also been observed by remote sensing techniques, using the SUMER telescope on the SOHO spacecraft. By comparing optical emission lines originating from the corona with lines from the CHROMOSPHERE, the existence of an FIP bias of $\sim$4 was observed in coronal plasmas above quiet equatorial regions from where the slow wind originates, while this factor was much smaller above coronal holes, from where the fast solar wind streams emanate, thus confirming the *in situ* measurements.

The same spectroscopic technique can even be applied to other stars than the Sun (but obviously only as a full-disk integration). The existence of an FIP effect was found in cool stars such as αCen AB and ϵEri, but not in the hotter star αCMi (Procyon).

FIP fractionation models

From the shape of the FIP fractionation curve, we obtain two key ingredients for the construction of models. (1) Any mechanism is to operate at a region in the solar atmosphere where it is (at least partially) neutral, or else it is not clear how the FIP (or FIT) could be a relevant parameter. Many different possibilities have been considered in the models for this 'mode of separation'. (2) The step near 10 eV suggests that photoionization by Lyman-α photons (10.2 eV) may play an important role (particularly for C, which has low-lying metastable levels that can be ionized by Lyman-α, whereas the ground state cannot). The flux in the Lyman-α line is more than a factor of 2 higher than the integrated flux at shorter wavelengths. Photoionization should therefore be included in any attempt to model the

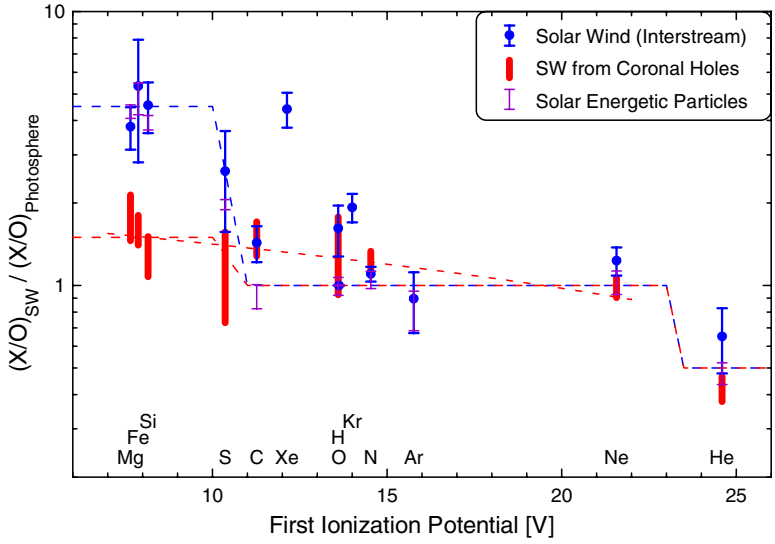

Figure 1. Abundances of elements measured in the solar wind relative to their photospheric abundances versus their FIP.

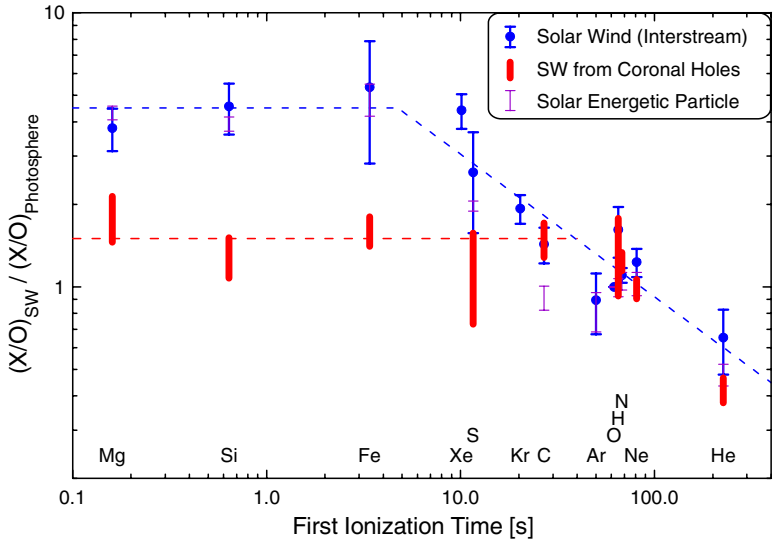

Figure 2. Abundances of elements from figure 1, plotted versus their FIT.

FIP fractionation, and most models indeed use it for the 'mode of ionization'.

Over the past decade, several models have been proposed to explain the observed FIP fractionation, most of which operate by ion–neutral separation in the chromosphere, predominantly by diffusion perpendicularly to a magnetic field. Geiss, in 1982, has shown that ion–neutral separation is much more effective than ion–ion separation and gives quantitative estimates for the conditions under which it could take place: temperature $T \lesssim 10^4$ K and density $n \lesssim 10^{16}\,\mathrm{m}^{-3}$, i.e. in the upper chromosphere and lower transition region. The density estimate was obtained with gravity as the only driving force for the diffusion of neutrals; if other driving forces are considered, the limit on n may be higher.

The first attempt was to consider a model in which ions and neutrals separate in the chromospheric canopy, where the magnetic field is horizontal, 1000–2000 km above the photosphere. Neutral atoms may settle downward, driven by gravity, but the diffusion of ions is impeded by the field. This reduces their diffusion velocity by a factor of $(1 + \omega^2 t_{\mathrm{col}}^2)^{-1}$, where ω is the gyrofrequency and t_{col} is the typical time between collisions. The degree of ionization of the elements considered was not calculated self-consistently in this model, but rather taken from an existing non-LTE model atmosphere. It was found that an FIP-dependent fractionation may indeed be obtained in such a model, but the resulting diffusion times needed to

separate the species are much larger—hours to days—than the typical lifetime of structures in the solar atmosphere. This was not surprising, as the density in the adopted model atmosphere was higher throughout the considered region than the limiting density for gravity-driven ion–neutral separation mentioned above. The idea may be saved by taking a dynamical approach along the same line, in which the horizontal magnetic field is rising from the photosphere through the chromosphere and into corona, lifting an overabundance of low-FIP elements (the 'skimmer' model). Preliminary results look quite promising if a field of 5 G at a velocity of 5 km s^{-1} is considered.

In a quite complementary approach, the excitation and ionization of elements under chromospheric conditions were explicitly investigated, at first without specifying the mechanism of ion–neutral separation. A neutral gas mixture is exposed to the solar spectrum in an optically thin environment. Excitation and ionization by photons made the main contribution, but collisional ionization by electrons ($n_e = 10^{16}$ m^{-3}, $T_e = 10^4$ K) as well as radiative recombination are also taken into account. The resulting FIT (used in figure 2) suggest that any separation of neutrals from ions has to occur on short time scales of the order of 1 min, as this is the typical ionization time of high-FIP elements once they become exposed to the EUV radiation from the corona. This in turn suggests that the separation is to operate on small length scales, in order to keep the relative velocities within reasonable limits.

The first attempt to construct a model considering both ionization and separation operated on an initially neutral gas mixture of photospheric composition and uniform temperature, concentrated in narrow, vertical or nearly-vertical magnetic structures. The gas mixture is assumed to rise along the magnetic field, and at the same time to become excited and ionized by EUV photons and by electrons; radiative recombination is also considered. The newly created ions remain attached to the magnetic field, i.e. trapped in the upward flow. The neutrals, on the other hand, are driven across the field lines by an initial density gradient and lost in a downward stream outside the structure under consideration. Thus the resulting gas mixture exiting at the top of the structure is enriched in low-FIP elements, since they have been ionized more quickly, and fewer neutrals were lost from the structure. The resulting gas mixture obtained in a typical model run compares favorably with the slow solar wind composition: not only is the step between low-FIP and high-FIP elements reproduced, but also the critical elements near this step, C and S, are obtained partially enriched, as observed, and even the 'FIP exceptions', Kr and Xe, result roughly with their observed enrichment. The model parameters were $n = 10^{15}$ m^{-3}, $T = 10^4$ K, and $d = 10$ km (d is the width of the considered structure). Moreover, the reduced step height observed in fast streams can also be accounted for by the model: it is sufficient to consider less narrow structures, of the order of 30–100 km, to obtain an FIP step height of a factor of 2 only. This may be interpreted with a chromospheric structure that could be coarser beneath coronal holes than under closed field regions. However, the model has been criticized, less for the need of an (as yet) unobservable chromospheric fine structure and of a specific geometry in which the mechanism operates, but for its need of relatively low densities, because at $n \gtrsim 10^{16}$ m^{-3} the reduced mobility of the neutrals would no longer allow them to leave the considered structure.

A few authors have tried to overcome this difficulty by constructing a similar model, which was retaining the careful treatment of ionization and collisions of the one described above, but considering a less specific model geometry. The fractionation was obtained by diffusion across a horizontal slab, again along a (nearly) vertical magnetic field. For specific, but naturally chosen, boundary conditions at the slab interfaces, the observed FIP fractionation pattern in the slow solar wind with a step height of ~5 was obtained at the upper slab interface, as was the depletion of helium relative to the high-FIP elements. The crucial boundary condition is that the flux at the top of the slab is the same for each heavy ion species in natural units: density normalized to one at the slab bottom, and velocity expressed in units of the natural diffusion speed, $(D\tau)^{1/2}$, where D is the diffusion constant in the ambient main gas and τ is the ionization time. The fractionation obtained in this model was found to be almost independent of the background density and temperature for realistic chromospheric conditions. On the other hand, the agreement for Kr and Xe is less good than it had been in the model described above. Moreover, an adaption of the model to yield the reduced FIP bias observed in fast streams is not straightforward either. It could possibly be obtained by arguing that diffusive equilibrium is not quite reached beneath coronal holes, resulting in an incompletely fractionated mixture being output at the top of the slab and into the fast solar wind.

A class of recently proposed models works with diffusion driven by electromagnetic forces, either (1) by dragging ions into a chromospheric gas parcel that is to be supplied to the corona or (2) by expelling neutrals out of such a parcel. A mechanism of type (1), investigated qualitatively, considers a small region of the chromosphere being heated by downward heat flux from the corona along a magnetic flux tube, leading to localized evaporation and lifting of chromospheric material. This, in turn, produces a horizontal thermoelectric field, dragging ions from the surroundings into the uplifting region. This leads to an accumulation of low-FIP elements in that region, since they are already ionized in the surroundings, whereas the high-FIP ions still are predominantly neutral there. A mechanism of type (2) was investigated, again qualitatively, by considering a cylindrically symmetric magnetic field structure in a partially ionized atmosphere, and calculating the system of direct currents created by such a configuration. It could be shown that, near the periphery of the flux tube, there is a strong diffusion of neutrals relative to the ions out of the structure, which may produce the observed FIP fractionation. However,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

this class of models has yet to be worked out quantitatively and to make predictions that can be compared with the observations (see also SOLAR PHOTOSPHERIC MAGNETIC FLUX TUBES: OBSERVATIONS; THEORY).

Finally, the FIP fractionation may be caused, or supported, by waves on a magnetic field in a partially ionized gas mixture, an idea put forward already in 1989. Such waves could heat the mixture and thus lead to the preferential loss of neutrals while the ions remain bound to the field. Again, in order to assess the value of this idea, quantitative predictions are needed, but no worked-out models of this kind exist in the published literature as yet.

In summary, none of the nearly a dozen FIP fractionation models that have been published is without its shortcomings, and much detailed work remains to be done in order to pinpoint the location and the mechanism(s) producing the observed FIP fractionation.

Trans-Neptunian Object (TNO)

An outer Solar System object whose orbit has a semi-major axis greater than that of Neptune (30.1 AU). Such objects comprise the Kuiper Belt. They are given asteroidal designations, though they are not asteroidal in nature, but most likely planetesimals that have remained unmodified since the early history of the Solar System. The TNOs are often classified according to their orbital characteristics. The first group, which accounts for about 50% of known TNOs, are known as 'classical' Kuiper Belt objects, or *cubewanos*—after the designation of the first to be discovered, 1992 QB_1. These objects have orbits of quite low eccentricity and mean radius 42–47 AU. About 40% of TNOs are, like Pluto, in a 3:2 resonance with Neptune in orbits of mean radius 39 AU: for every three orbits of Neptune, they complete two. For this reason they are sometimes referred to as *plutinos*. This 'resonant' class also includes objects having other orbital resonances with Neptune: about 5% of TNOs show a 2:1 resonance and have mean radius 48 AU; other objects have a 4:3 or 5:3 resonance. There are also a small number of so-called *scattered disk objects* (SDOs), characterized by high eccentricities, the best-known example being 1996 TB_{66}, whose distance from the Sun varies from about 35 to 135 AU. Such objects are surmised to have been perturbed, early in the history of the solar system, from their original orbits in the Uranus–Neptune region of the Kuiper Belt. The orbits of SDOs are dynamically similar to those of the Centaurs, with which they are sometimes grouped. By April 2000 a total of 270 TNOs had been found. It is estimated that there may be ten thousand of them 200 km in size.

In 2001, a trans-neptunian object known as 2001 KX76 was discovered that may be the largest minor body in the solar system. Its diameter, which is not very well determined, lies in the region of 1200 km, possibly even 1400 km. This makes it significantly larger than CERES. Ceres, the first asteroid (minor planet) to be discovered in the solar system, has held the record as the largest known object of its kind for two centuries with a diameter about 950 km.

Trapezium

The multiple star θ^1 Orionis, in the heart of the Orion Nebula, visible when viewed directly with moderately powerful telescopes and on short-exposure photographs of the nebula; it can be seen on long-exposure photographs only where image-improving techniques have increased the contrast with the surrounding nebulosity. It consists of four stars arranged in a pattern resembling an irregular trapezium, with sides ranging from 8.6″ to 18.4″ and diagonals of 16.9″ and 20.6″.

Identification of the individual stars can be rather confusing; they were formerly designated θ^1 Ori A, B, C and D in order of increasing right ascension; in the *Hipparcos Catalog*, however, they are lettered in order of decreasing brightness. Clockwise from the southernmost component they are now designated A (formerly C), C (formerly D), D (formerly B) and B (formerly A). Their apparent magnitudes are A, 4.96; B, 6.35; C, 7.20; D, 7.49.

The faintest component, θ^1 Ori D, is an eclipsing binary with a period of 6.5 days and is also known as BM Orionis; θ^1 Ori B has recently been discovered to be an eclipsing binary also, with a period of 65.4 days. All four components are hot, blue-white stars of spectral types O and B, and together with several other fainter stars in the region form an embryonic cluster of stars newly formed from the nebular material.

Triangulum

(the Triangle; abbrev. Tri, gen. Trianguli; area 132 sq. deg.) A northern constellation which lies between Andromeda and Aries, and culminates at midnight in late October. Its origin is uncertain, though the ancient Greeks likened it to a capital delta (Δ) and it was also associated with the Nile delta and the island of Sicily. Its brightest stars were cataloged by Ptolemy (*c.* AD 100–175) in the *Almagest*.

A small but distinctive constellation, the brightest stars of Triangulum, β Trianguli, magnitude 3.0, α Trianguli (Mothallah), magnitude 3.4, and γ Trianguli, magnitude 4.0, form a narrow isosceles triangle, with α at the apex. Interesting objects include 6 Trianguli, a multiple star system with yellow (G5) and pale yellow (F5) components, magnitudes 5.3 and 6.8, separation 3.9″, each of which has an unseen companion that revolves around its primary in 14.73 days and 2.24 days, respectively, and the Triangulum Galaxy (M33, NGC 598, sometimes called the Pinwheel Galaxy), a sixth-magnitude spiral galaxy and member of the Local Group, about 2.6 million light-years distant.

Triangulum Australe

(the Southern Triangle; abbrev. TrA, gen. Trianguli Australis; area 110 sq. deg.) a southern constellation which lies between Norma and Apus, and culminates at midnight in late May. It was first shown in Johann Bayer's atlas *Uranometria* of 1603, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7. Another southern triangle, Triangulus Antarcticus, was shown to the south of Argo Navis on a celestial globe by the Dutch theologian and geographer Petrus Plancius in 1589, but was never accepted.

A small but conspicuous constellation, Triangulum Australe is easily recognized by virtue of its three brightest stars, α Trianguli Australis (Atria), magnitude 1.9, β Trianguli Australis, magnitude 2.8, and γ Trianguli Australis, magnitude 2.9, which form an almost equilateral triangle. Other bright stars include δ Trianguli Australis, magnitude 3.9, and ε Trianguli Australis, magnitude 4.1. Interesting objects include NGC 6025, an open cluster of about 60 stars, the brightest of which is of magnitude 7.3.

Triangulum Galaxy

A nearby spiral galaxy in the constellation of Triangulum. Otherwise known as M33, it is a face-on spiral that lies at a distance of 2500 000 light-years (slightly further away than the much larger Andromeda Galaxy) and is a member of the Local Group of galaxies. With a diameter of about 40 000 light-years and a population of about 15 billion stars, it is about half the size, and has about one-tenth of the mass, of the Milky Way Galaxy. With a relatively small central bulge and open spiral arms, which contain numerous HII regions and young star clusters, it is classified as an Sc galaxy within the Hubble classification scheme. Its core contains a bright, variable, x-ray source, which may be powered by a central black hole.

Trieste Astronomical Observatory

Founded in 1866 as the Austrian K. u. K. Maritimes Observatorium, in 1898 the Trieste Astronomical Observatory became an independent institute for research in astronomy. Now it is part of INAF (Istituto Nazionale di Astrofisica) and the Italian council for research in astrophysics. Staff include 20 researchers and 42 technicians and administrators. Research fields are extragalactic, stellar physics, solar radioastronomy (10 m antenna), solar system astrophysics, astrophysical technologies for ground-based and space astronomy, international cooperation projects. The facilities include an astronomical library, museum and public observatory.

Trifid Nebula (M20, NGC 6514)

An emission nebula in the constellation Sagittarius, position RA 18^{h} 02.6^{m}, dec. $-23^{\circ}\,02'$. It is of ninth magnitude, with quite a high surface brightness, and measures $29'$ by $27'$. It surrounds the multiple star HN 40, the light of whose brightest members energize the nebula. The Trifid gets its name from dark lanes that trisect it.

Triton

Triton is the largest satellite of NEPTUNE. It was discovered in 1846, a few weeks after Neptune. Its orbital motion was soon established, but its physical and chemical properties remained basically unknown until the Neptune encounter of the VOYAGER 2 spacecraft in August 1989.

The orbit of Triton, which is nearly circular, is retrograde and shows a high inclination (157°) which suggests that this satellite was captured by Neptune's gravity field, rather than formed in the Neptunian proto-subnebula. The high inclination of Triton's orbit, combined with Neptune's obliquity, leads to large and complex periodic variations of the latitude of the subsolar point, which ranges between +52° and −52°. These large variations induce very large seasonal effects, probably the strongest ever observed on a solar system object. As in the case of the Moon and the Galilean satellites, Triton's orbit is synchronous, so that the satellite always turns the same hemisphere towards Neptune.

Prior to Voyager observations, little was known about Triton's chemical composition. Ground-based spectroscopy in the infrared range had detected the presence of methane and nitrogen ices which suggested the presence of a nitrogen-rich atmosphere, but the surface pressure of this atmosphere was completely unknown.

Voyager observations of Triton, in August 1989 have provided us with a determination of its diameter (2700 km), its density (2.08 g cm^{-2}), its surface temperature (38 K), its surface pressure (14 μbar) and its atmospheric chemical composition (molecular nitrogen with traces of methane at the 0.01% level). The presence of a stable atmosphere is unusual on an object as small as Triton; this stability is due to the very low temperature of Triton's surface which inhibits gravitational escape.

Voyager images also revealed the extraordinary aspect of Triton's surface. The very high albedo of Triton (0.7 in the visible range) puts the satellite among the most reflective of solar system objects. The Voyager images mostly covered the southern hemisphere. They showed a bright polar cap extending widely around the south pole. North of this polar cap, a rugged terrain, reminiscent of the skin of a cantaloupe melon, is cross-cut by a pattern of intercepting ridges, possibly the remnants of a past TECTONIC event. Triton's surface shows relatively few impact CRATERS, which implies that it is relatively young. A more cratered region, near the equator, shows an impact density comparable to the 3-billion year-old lunar maria. The chemical composition of Triton's surface was identified from ground-based infrared spectroscopy after the Voyager flyby. Ices of N_2, H_2O, CO_2, CO and CH_4 were detected. The abundance of gaseous nitrogen, and thus the surface pressure of Triton, is consistent with equilibrium with the solid phase.

In spite of its very low density, the atmosphere of Triton exhibits several characteristics which are unique in the solar system. The temperature profile consists of a troposphere up to an altitude of 8 km where the temperature is minimum. Above the tropopause, the thermosphere starts immediately, without the presence of an intermediate radiative stratosphere, which is usually found in PLANETARY ATMOSPHERES. In the thermosphere, the temperature increases by conduction up to an altitude of about 400 km where ionization takes place. Several traces of condensates were detected by Voyager in the lower troposphere. They are presumably due to methane and hydrocarbons produced by methane photodissociation; nitrogen clouds were also observed above the southern polar cap which is at present exposed to maximum solar insolation and is sublimating part of its nitrogen ice.

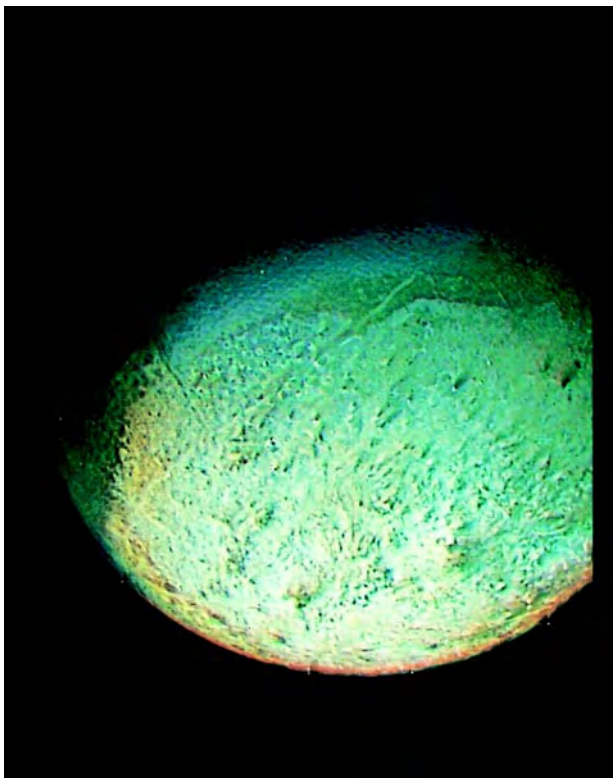

Figure 1. The southern hemisphere of Triton as observed by Voyager 2 in August 1989. The southern polar cap extends widely around the south pole. Dark plumes are detectable over the bright surface of the polar cap.

Seasonal effects are very strong on Triton, due to the high inclination of the satellite. Climatic variations involve the condensation of the two major atmospheric species, nitrogen and methane, which are both involved in the formation of the polar caps. This situation may be compared to the Martian atmosphere, with CO_2 and H_2O acting respectively on Mars like N_2 and CH_4 on Triton (see MARS: ATMOSPHERE).

As in the case of Mars, seasonal effects induce on Triton large-scale dynamical motions. Some of these dynamical motions are illustrated by the detection of active plumes in Voyager images of Triton's surface. These plumes were observed as dark trails, rising vertically

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

up to an altitude of 8 km and then trailing to the west over more than 100 km. Four of these plumes were observed by Voyager in a continuously illuminated region close to the subsolar point. Several interpretations of these phenomena have been suggested, including active volcanism and solar-driven geysers.

Apart from Triton's density, we have little information about its interior. According to models, the internal structure of Triton could consist of a core of metals and rocks, surrounded by a mantle of water ice covered with a variety of ices: CO_2, H_2O, possibly NH_3, CO, CH_4 and N_2, the two latter ices being transported into polar caps along the seasonal cycle.

What could be the origin of Triton? Its striking similarity with Pluto, in terms of size, density, surface chemical composition and atmospheric composition, suggests a common origin for the two bodies (see PLUTO AND CHARON). It is now believed that Pluto is the biggest representative of the newly discovered class of KUIPER BELT objects which populate the outer solar system at heliocentric distances larger than 30 AU. Triton, like Pluto, most probably originated from the Kuiper Belt and was later captured by Neptune's gravity field. Such a capture, however, is only temporary unless sufficient energy is dissipated in the process. Moreover, the probability of such a capture is quite small, so this scenario suggests the presence of a large number of triton-size PLANETESIMALS coming from the kuiper Belt in the early stages of solar system history.

Trojan Asteroids

Two groups of asteroids whose orbital elements are similar to those of Jupiter. One group orbit ahead of Jupiter, clustered around the L_4 Lagrangian point, while the other group orbit behind the planet, around the L_5 Lagrangian point. The L_4 group, which are more numerous, are sometimes called the *Achilles group*, after the first Trojan to be discovered, (588) Achilles. The L_5 group are sometimes called the *Patroclus group*, after the second Trojan discovery, (617) Patroclus. Achilles and Patroclus are both around 150 km in diameter, and were both found in 1906. The largest Trojan is (624) Hektor, at 225 km; the names given to Trojans are those of heroes from Homer's writings on the Trojan Wars. As of April 2000 there were 425 known Trojans in the L_4 group, and 188 in the L_5 group. Two Martian Trojans have also been found.

Perturbations by other planets cause Jupiter's Trojans to oscillate about the Lagrangian points. An individual Trojan will drift back and forth in longitude by 15° to 20° either side of its Lagrangian point with a period of up to 200 years. Trojans have low albedos, in the range 0.02–0.07. About 60% are D-type, with reddish reflectance spectra indicating a carbon-rich surface; most of the others are C-type, with compositions similar to carbonaceous chondrites, and the remainder P-type, with quite red surfaces indicating an organic surface composition.

Troughton, Edward (1753–1836)

Instrument-maker, born in Corney, Cumberland, England, designing instruments to aid navigation, surveying and astronomy. With his brother John, in their family business in London, he made transit circles for Greenwich and other observatories, buying in the optics from, for example, the Dollonds, because the family trait of color-blindness meant that they were unable to test lenses. Troughton invented a method to make accurate scales by dividing a circle.

Trumpler, Robert Julius (1886–1956)

Astronomer, born in Zürich, Switzerland. He worked at the Lick Observatory in California, where he showed that distant clusters of stars are systematically too faint for their size, as if dimmed by an obscuring medium whose effects accumulate with distance. This was the first convincing evidence of the presence of an interstellar medium in our Galaxy, consistent with the indications from HEBER CURTIS' recognition that spiral galaxies seen edge-on had obscuration along their central plane.

Tucana

(the Toucan; abbrev. Tuc, gen. Tucanae; area 295 sq. deg.) a southern constellation which lies between Indus and Hydrus, and culminates at midnight in mid September. It was first shown on a celestial globe by the Dutch theologian and geographer Petrus Plancius in *c*.1598, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7.

A small, rather inconspicuous constellation, the brightest stars in Tucana are α Tucanae, magnitude 2.9, β Tucanae, a multiple system consisting of a wide pair of bluish-white (B9 and A2) components, magnitudes 4.4 and 4.5 (combined magnitude 3.7), separation 27″, both of which have a fainter companion, the former of magnitude 13.6, separation 2.4″, the latter white (A7), magnitude 6.0, separation 0.1–0.6″, period 44.4 years, and another bluish-white (A2) component 10′ to the southwest, which is also double, with components of magnitudes 5.8 and 6.0 (combined magnitude 5.2), separation 0.1″, all six stars having a similar proper motion, and γ Tucanae, magnitude 4.0. Another interesting star is κ Tucanae, a quadruple system consisting of pale yellow (F6) and orange (K1) components, magnitudes 5.0 and 7.7, separation 5.0″, and a yellow (G5) component, magnitude 7.9, 320″ distant, which has a magnitude 8.4 companion, separation 0.9–1.1″, period 86.2 years.

Other interesting objects in Tucana include the Small Magellanic Cloud, 47 Tucanae (NGC 104), the second most impressive globular cluster in the sky (after ω Centauri), visible to the unaided eye as a fuzzy fourth-magnitude star, and NGC 362, another globular cluster, of seventh magnitude.

Tully–Fisher Relation

Cepheid variable stars are the primary means by which distances are measured over the local volume of space. However, beyond about 20 megaparsecs (Mpc) Cepheids become too faint, even for Hubble Space Telescope, and so alternative means of measuring distances are needed. One of the more popular secondary methods makes use of the strong correlation between the luminosity of SPIRAL GALAXIES and their rotational velocities. This is known as the Tully–Fisher relation.

The Tully–Fisher relation has become one of the most widely used methods of measuring extragalactic distances since spiral galaxies are relatively common and contain young, massive stars. As a result, they also contain Cepheid variables, making the calibration of the Tully–Fisher relation using nearby systems relatively straightforward. In applying this technique the rotational velocity serves as a predictor of the luminosity, or absolute magnitude, of the galaxy. The distance is then calculated from the distance modulus, the difference between the apparent magnitude and the predicted absolute magnitude of the galaxy. The Tully–Fisher relation provides an opportunity to step from the local calibrating galaxies to the smooth Hubble expansion in a single step. Consequently, this technique is extremely valuable for the mapping of large-scale structure, the Hubble flow and any associated peculiar (i.e. non-expansion) velocities.

The origin of the Tully–Fisher relation remains somewhat uncertain but arises from the correlation between mass and luminosity. A spiral galaxy rotates under the influence of its own gravity and so the rotational speed is connected with its mass. A more massive galaxy also contains a larger number of stars and is therefore more luminous. The result is a correlation between the luminosity and the rotational speed for spiral galaxies, the Tully–Fisher relation. There are a few complications to this simple explanation. First, the total luminosity of a particular spiral galaxy is a reflection of its star formation history. This might be expected to vary from galaxy to galaxy. Second, the fact that spiral galaxies have considerable amounts of 'DARK MATTER' means that the mass of a galaxy is not necessarily well represented by the amount of mass contained within its population of stars. That is, the ratio of mass to light for spiral galaxies might be expected to vary at a given total mass. The fact that the Tully–Fisher relations show relatively small scatter indicates that these variations are small and this in turn provides a strong constraint on models for the formation and evolution of spiral galaxies. While these details are still uncertain we can still measure galaxy distances through an empirical calibration of this relation.

Observational data for the Tully–Fisher relation

The necessary observational data consist of apparent magnitudes, corrected for Galactic and internal extinction by dust, and some measure of rotational velocities, corrected for projection effects. Usually, the rotational velocity is measured via the Doppler broadening of the H I 21 cm line, since spiral galaxies are easily detected in this spectral line using RADIO TELESCOPES. However, for galaxies with REDSHIFTS of only a few thousand km s^{-1}, the 21 cm line is shifted into heavily used regions of the radio spectrum, resulting in severe interference from terrestrial sources (radars, cell phones, etc). In addition, at this wavelength the resolution of even the largest single-dish radio telescopes is only a few arcminutes and so for redshifts beyond about 5000 km s^{-1} the detected signal can be confused with that from neighboring galaxies. This has prompted interest in using optical emission lines such as Hα to measure the rotational speed of spiral galaxies.

Early application of the Tully–Fisher relations used photographic photometry, but today CCDs are the detectors of choice at optical wavelengths owing to their superior performance. The redder Johnson bandpasses (R and I) are usually used because of their reduced sensitivity to dust extinction and because the spectral energy distributions of spiral galaxies are dominated by late-type giant stars at these wavelengths. Thus, these measurements are less sensitive to variations in the star formation history and dust content of the individual galaxies. These advantages continue into the near-infrared H and K bands. However, the night sky at these wavelengths is as much as a factor of 10^4 brighter than at optical wavelengths, making accurate surface photometry at faint levels extremely difficult.

A typical procedure for measuring the magnitude of a galaxy from a calibrated CCD image begins by identifying and masking contaminating regions from foreground stars, background galaxies and cosmetic defects. The surface brightness profile of the galaxy is constructed by binning pixels as a function of radius. The integrated magnitude within some surface brightness level can then be computed and this measurement extrapolated to infinite radius using some model, such as an exponential, to produce a total magnitude for the galaxy. Ellipses are often fitted to the isophotes of the galaxy to yield the best-fit axial ratio of the inclined disk as a function of radius and surface brightness. The axial ratio can then be used to estimate the inclination of the galaxy.

There are several advantages to using the Doppler-broadened 21 cm line of H I as the measure of the rotation of late-type galaxies. First, spiral galaxies are H I rich so the line is extremely strong. Second, the H I within these systems has an extended distribution such that the outer, flat portion of the rotation curve is well sampled, providing an accurate measurement of the maximum rotational velocity. However, low angular resolution and interference become significant limitations at redshifts of $\sim$10 000 km s^{-1}, as described above. The use of the Hα emission line avoids these issues. In this case, the slit of a spectrograph is positioned to lie along the long axis of a DISK GALAXY such that the resulting spectrum will sample the velocity as a function of radius for the galaxy. However, since the Hα emission line is produced within regions of active STAR FORMATION, the outer regions of spiral

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

galaxies may not have enough Hα emission to be detected. This can result in the outer, flat portion of the rotation curve of lower-luminosity galaxies not being adequately sampled since these systems generally have slowly rising rotation curves. Thus, 21 cm measurements are usually the best choice for nearby galaxies and Hα measurements are optimal for redshifts beyond about 10 000 km s^{-1}. For redshifts beyond about 0.2 (60 000 km s^{-1}) the Hα line becomes contaminated by increasingly strong emission lines from the night sky (mostly due to OH). This has prompted investigations into whether other lines such as [O II] (λ 3727 Å) and [O III] (λ 5007 Å) could be used such that the Tully–Fisher relation could be applied at larger distances. The preliminary results appear to be very promising and efforts are underway to use the Tully–Fisher relations to examine the structural and evolutionary properties of GALAXIES AT HIGH REDSHIFTS.

Inclination corrections to the observational data

Some method of measuring galaxy inclinations is required in order to correct the magnitudes for internal extinction and the observed rotation for projection. Assuming that all spiral galaxies can be adequately represented as an oblate spheroid with the same intrinsic flattening, the inclination can be calculated from the projected shape of the disk. Specifically,

$$\cos^2 i = \frac{(b/a)^2 - \alpha^2}{1 - \alpha^2}$$

where i is the inclination, b/a is the observed axial ratio of the best-fitting ellipse and α is the intrinsic axial ratio for an edge-on system. Complications arise from the fact that some galaxies do not have perfectly circular isophotes at face-on orientation. As a result, most investigations restrict the sample to those systems whose inclinations are at least 30°–45° in order to minimize the resulting uncertainties on the deprojected rotational velocities.

The parameter of choice for predicting the luminosity of a disk galaxy is $V_{\rm max}$, the maximum amplitude of the rotation curve. This is especially convenient given that most galaxies have flat rotation curves over much of their extent. Tully and Fisher advocated using the Doppler width of the 21 cm line profile measured at 20% of peak intensity (W_{20}), corrected for inclination. That is, $W^{\rm i}_{\rm R} = W_{20}/\sin(i) \sim 2V_{\rm max}$. However, if the Tully–Fisher relation is to be applied to low-luminosity spiral and irregular galaxies a more complicated correction is required in order to account for the effects of internal turbulence and subtle variations in line-profile shape. However, for $W^{\rm i}_{\rm R} >$ 150 km s^{-1} these corrections are negligible. When optical spectra are used $V_{\rm max}$ can be measured directly from the rotation curve.

Historically, the internal extinction with disk galaxies has proven to be a difficult problem. However, the advent of CCDs and infrared detectors has allowed accurate photometry of galaxies over a broad range in wavelength enabling the amount of extinction to be statistically estimated from the amount of reddening. The extinction corrections to the magnitudes are often expressed in terms of the observed axial ratio. Specifically, $A^{\rm i}_{\lambda} = \gamma_{\lambda} \log(a/b)$, where λ is the wavelength of the observation in the standard bandpasses and a/b is the observed axial ratio. The dependence of this correction on the luminosity of the galaxy, due to variations in dust content, etc, can also be described by expressing γ_{λ} in terms of the projection-corrected rotational velocity (W^i_R). A representative result is

$$\gamma_B = 1.57 + 2.75(\log W^{\rm i}_{\rm R} - 2.5)$$

$$\gamma_R = 1.15 + 1.88(\log W^{\rm i}_{\rm R} - 2.5)$$

$$\gamma_I = 0.92 + 1.63(\log W^{\rm i}_{\rm R} - 2.5)$$

$$\gamma_H = 0.43 + 0.76(\log W^{\rm i}_{\rm R} - 2.5)$$

where the subscripts on γ represent the standard bandpasses. Here, $W^{\rm i}_{\rm R} \sim 2V_{\rm max}$ and $V_{\rm max}$ is the amplitude of maximum rotation within a galaxy.

The apparent magnitudes also require correction for Galactic extinction. In the past, this has been a difficult problem. However, there now exist extensive maps of both the neutral hydrogen gas (H I) and the distribution of dust (IRAS 100 μm) within the Galaxy. The good correspondence between these two maps indicates that the H I gas and dust trace each other. The amounts of the extinction which correspond to these two components have been calibrated from detailed, multicolor observations of distant stars. As a result, the Galactic extinction for any galaxy can be estimated given its position on these maps. As the Galactic latitude falls below about 25–30°, the corrections for Galactic extinction become large with correspondingly large uncertainties. Therefore, most investigators limit the application of the Tully–Fisher relation to galaxies above this latitude.

Absolute calibration of the Tully–Fisher relation using Cepheids

Ground-based Cepheid surveys are extremely difficult because the Cepheids in all but the nearby Local Group galaxies are very faint and subject to significant contamination by neighboring stars. However, the advent of Hubble Space Telescope has allowed the detection of Cepheids within galaxies out to about 20 Mpc in distance and enabled the number of calibrating systems to be significantly increased. A large effort to obtain Cepheid distances to a number of nearby galaxies, known as the Hubble Key Project of Extragalactic Distances, and a similar project to obtain Cepheid distances to galaxies containing type Ia supernovae, has brought the number of galaxies suitable for calibrating the Tully–Fisher relation to 30 systems. Figure 1 shows the resulting Tully–Fisher relations for this calibration sample. A least-squares fit to these data gives the following relations:

$$M^{\rm b,i}_B = -7.41(\log W^{\rm i}_{\rm R} - 2.5) - 20.04 \pm 0.04 \quad (0.22)$$

$$M^{\rm b,i}_R = -8.09(\log W^{\rm i}_{\rm R} - 2.5) - 21.05 \pm 0.04 \quad (0.19)$$

$$M^{\rm b,i}_I = -8.55(\log W^{\rm i}_{\rm R} - 2.5) - 21.51 \pm 0.04 \quad (0.22)$$

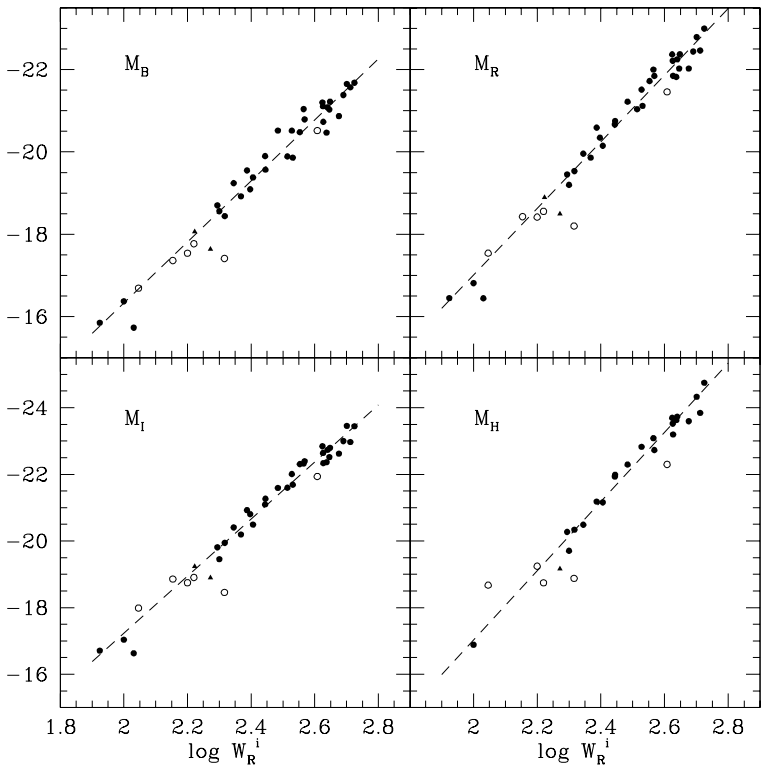

Figure 1. B, R, I and H band calibrations of the Tully–Fisher relation. Solid circles are galaxies with distances measured using Cepheids, solid triangles are galaxies with distances estimated via surface brightness fluctuation measurements within dE companions and open circles are systems thought to be group members with at least one galaxy with a Cepheid distance, and therefore thought to be at a similar distance. The dashed line is a least-squares fit to the solid points in each panel.

$$M_H^{\mathrm{b,i}} = -10.39(\log W_{\mathrm{R}}^{\mathrm{i}} - 2.5) - 22.22 \pm 0.08 \quad (0.30)$$

where the superscripts b and i indicate Galactic extinction and internal extinction corrections, respectively. The zero points give the absolute magnitude for galaxies with $\log W_{\mathrm{R}}^{\mathrm{i}} = 2.5$, or $V_{\max} = 160$ km s^{-1}. In all bandpasses, the random uncertainty in the zero point is negligible compared with the remaining systematic uncertainty in the absolute calibration of the Cepheids themselves (∼0.13 mag, or 7% in distance). The rms dispersions of the relations are given in parentheses. Given these calibrations, the absolute magnitude of any spiral galaxy can be predicted from its rotational velocity and its distance estimated from its measured apparent magnitude.

Application of the Tully–Fisher relation to field galaxies

The Tully–Fisher relations have been used to estimate the distances to several hundred spiral galaxies within an expansion velocity of about 8000 km s^{-1}. An example of the resulting 'Hubble flow' is shown in figure 2. Since the velocities are a combination of both the expansion and any local peculiar velocities induced by gravity, the deviations in velocity can be correlated with position on the sky to produce maps of the deviations from the mean expansion field. The primary features seen in such maps are (1) local streaming of ∼100 km s^{-1} associated with the non-uniform distribution of matter within 10 Mpc of the Local Group, (2) retarded expansion velocities of several hundred km s^{-1} near the Virgo cluster of galaxies and (3) a large-scale streaming of about 400 km s^{-1} towards a 'Great Attractor' located at a distance of about 60 Mpc in the direction of the Hydra–Centaurus cluster complex. These peculiar velocities are usually assumed to result from the gravitational accelerations produced by the irregularities in the large-scale distribution of mass. With this assumption, various research groups have used these 'flow maps' to constrain the mean mass density of the universe (Ω) as well as to examine the degree to which the distribution of galaxies follows the distribution of mass. These investigations appear to favor low values of Ω (∼0.2) and also imply that mass is generally traced by the distribution of galaxies.

Distant clusters and the Hubble constant

The errors in the distances of individual galaxies measured using the Tully–Fisher relations are about 15% when using high-quality observational data. As a result, the absolute errors can become large for distant galaxies. Since there are still significant peculiar velocities out to velocities of

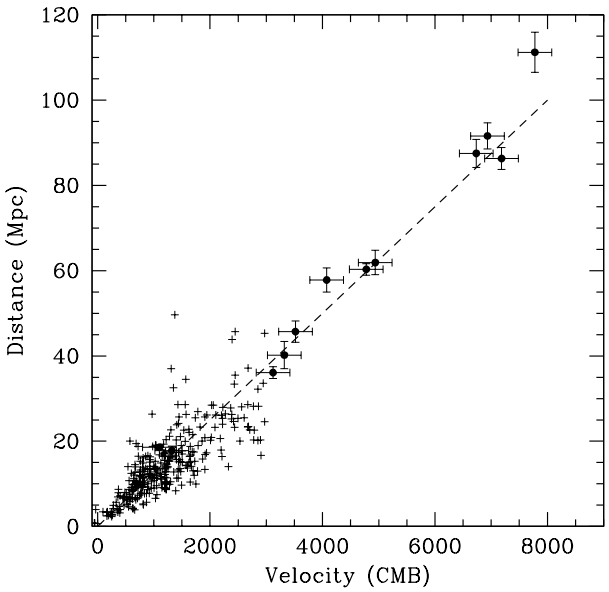

Figure 2. The velocity–distance relation, or 'Hubble flow', illustrating the expansion of the universe. The plus signs show the distances to individual, nearby galaxies measured using the Tully–Fisher relation. Since the errors are fractional (i.e. logarithmic), the absolute errors increase with distance and result in a cone-like spread of the data. The solid points with error bars represent the average distance and velocity for clusters. The cluster samples typically contain 15–20 galaxies, correspondingly reducing the errors. The dashed line shows a Hubble constant ($H_0 = V/D$) of 80 km s^{-1} Mpc^{-1}.

about 5000 km s^{-1}, large samples are needed at these distances in order to accurately sample the Hubble flow and map the distribution of peculiar velocities. Recent Tully–Fisher surveys using cluster samples have been used to measure the mean distances for a number of clusters over this volume. The mean distances and velocities of these clusters are shown in figure 2 along with those of the nearby field galaxies. Together, these data yield an estimated value of the HUBBLE CONSTANT of 77 ± 7 km s^{-1} Mpc^{-1}.

The inverse of the Hubble constant is related to the age of the universe. For a universe with zero density H^{-1} is equal to the age of the universe. If the universe has the 'critical density', i.e. $\Omega = 1$, then its age is $(2/3)H^{-1}$. At the present time, a typical estimate for the age of globular cluster stars is 14 ± 2 billion years. For comparison, the value of the Hubble constant given above corresponds to ages of 12.7 ± 1 and 8.5 ± 0.7 billion years for $\Omega = 0$ and $\Omega = 1.0$, respectively. At present, it appears that a cosmologically flat, critical universe is inconsistent with the observational data. This discrepancy has helped to generate interest in cosmological models with a non-zero COSMOLOGICAL CONSTANT Λ and, in particular, in cosmologically flat models with non-zero Λ. A cosmological constant is one way of reconciling these disparate estimates of the age of the universe.

Bibliography

The literature regarding the Tully–Fisher relation and its application to measuring extragalactic distances is extensive. A few representative papers are presented here.

Tunable Imaging Filters

While tunable filters are a recent development in night-time astronomy, they have long been used in other physical sciences, e.g. solar physics, remote sensing and underwater communications. With their ability to tune precisely to a given wavelength using a bandpass optimized for the experiment, tunable filters are already producing some of the deepest narrowband images to date of astrophysical sources. Furthermore, some classes of tunable filters can be used in fast telescope beams and therefore allow for narrowband imaging over angular fields of more than 1° over the sky.

The physics of tunable imaging

A rich variety of physical phenomena can isolate a finite spectral band: absorption, scattering, diffraction, evanescence, birefringence, acousto-optics, single-layer and multilayer interference, multi-path interferometry, polarizability and so on. Most of the available optical filter technologies are listed below (see also FILTERS):

linear or circular variable filter
multilayer dielectric filter
Fabry–Perot interferometer
Michelson interferometer
acousto-optic filter
solid etalon filter
solid Michelson filter
generalized resonant grating filter
sub-lambda evanescent grating filter
volume phase holographic grating filter
Lyot–Öhman filter
generalized Lyot filter
generalized Šolc[1] filter
liquid crystal filter

There is a bewildering array of future possibilities, including tunable crystal lattice structures, and many possible variants on the above technologies. Here, we focus on a few key technologies.

The ideal device

The ideal filter is an imaging device which can isolate an arbitrary spectral band $\delta\lambda$ at an arbitrary wavelength λ over a broad, continuous spectral range, preferably with a response function which is identical in form at all wavelengths.

The tilting interference filter is much the worst form of tunable filter. The spectral range covered is almost negligible, and the filter profile varies with tilt angle. Some devices (e.g. Lyot, linear variable filter) work only at a fixed resolving power but have the ability to tune over a wide spectral window. Better devices allow for a wide selection of resolving powers over a wide range of wavelengths.

The different techniques rely ultimately on the INTERFERENCE of beams that traverse different optical paths to form a signal. The technologies which come closest to the ideal tunable filter are the air-gap Fabry–Perot and Michelson (Fourier transform) interferometers. To understand why, we highlight the Taurus tunable filter (TTF) which was the first general-purpose such device for night-time astronomy (see http://www.aao.gov.au/local/www/jbh/ttf). This is a Fabry–Perot filter where interference is formed between two highly reflective, moving plates. To be a useful filter, not only must the plates move through a large physical range, but they must start at separations of only a few wavelengths, as we show.

The condition for photons with wavelength λ to pass through the filter is (see figure 1)

$$m\lambda = 2\mu\ell\,\cos\theta \tag{1}$$

from which it follows that

$$\frac{\mathrm{d}\mathcal{R}}{\mathcal{R}} = \frac{\mathrm{d}m}{m} = \frac{\mathrm{d}\ell}{\ell}. \tag{2}$$

For an order of interference m, the resolving power is $R = m\mathcal{N}$ where $\mathcal{N}$ is the instrumental finesse. The finesse is determined by the coating reflectivity and is essentially the number of recombining beams. For the TTF, the plates can be scanned over the range $\ell = 1.5$–$15\ \mu$m, and the orders of interference span the range $m = 4$–40, such that the available resolving powers are $R \approx 100$–1000.

The sharp core of almost all tunable-filter transmission profiles is not ideal. Even a small amount of flatness at peak transmission can ensure that we avoid narrowly missing most of the spectral line signal from a source. In theory, all band-limited functions can be squared off, but in practice this is difficult for all but two devices. Since the Michelson interferometer (filter) obtains its data in the frequency domain, the profile can be partially squared off at the data reduction stage through a suitable choice of convolving function. For the Šolc filter, the instrumental profile can be modified through the use of partial polarizers and birefringent retarder elements.

Summary of filter technologies

Here, we provide a brief outline of some of the key technologies.

Monolithic filters

Interference filter. The principle relies on a dielectric spacer sandwiched between two transmitting layers (single cavity). The substrates are commonly fused silica in the ultraviolet, glass or quartz in the optical and water-free silica in the infrared. Between the spacer and the glass, surface coatings are deposited by evaporation which partly transmit and reflect an incident ray. Each internally reflected ray shares a fixed phase relationship to all the other internally reflected rays. For constructive interference, for a wavelength λ to be transmitted, it must satisfy equation (1) where $\theta = \theta_{\mathrm{R}}$ is the refracted angle within the optical spacer, and the optical gap is the product

[1] The proper Czech pronunciation is 'Sholtz'.

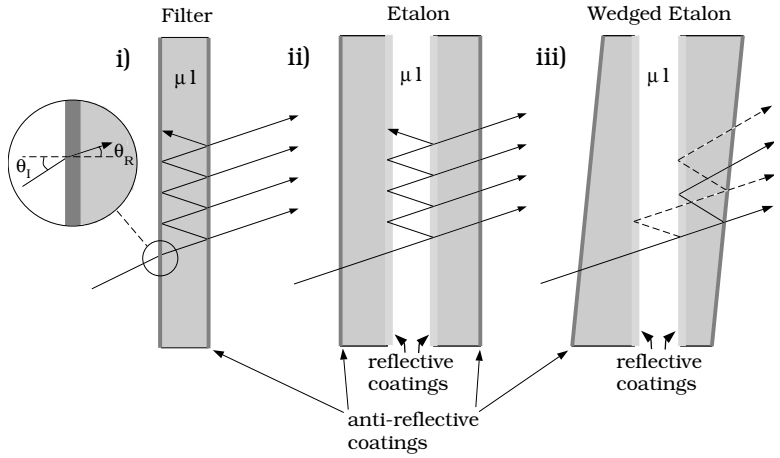

Figure 1. (i) Interference filter: the internal structure is not shown. (ii) Fabry–Perot etalon. (iii) Wedged Fabry–Perot etalon which avoids the problem of the plates behaving like interference filters.

of the thickness ℓ and refractive index μ of the spacer. The construction of these filters has undergone a revolution through the use of dielectric, multilayer thin-film coatings, and a proper description is more involved. All such filters can be tuned through a small wavelength interval ($\delta\lambda/\lambda = -\theta_R^2/2\mu^2$), which amounts to no more than 2%λ in practice. Suffice it to say, interference filters make for poor tunable devices.

Gap-scanning filters

Fabry–Perot filter. The air-gap etalon, or Fabry–Perot filter, was introduced in the previous section. The etalon comprises two plates of glass kept parallel over a small separation where the inner surfaces are mirrors coated with high reflectivity $\Re$. The transmission of the etalon to a monochromatic source λ is given by the Airy function

$$\mathcal{A} = \left[1 + \frac{4\Re}{(1-\Re)^2}\sin^2(2\pi\mu\ell\cos\theta/\lambda)\right]^{-1} \qquad (3)$$

where θ is the off-axis angle of the incoming ray and $\mu\ell$ is the optical gap. The condition for peaks in transmission is given in equation (1). Note that λ can be scanned physically in a given order by changing θ (tilt scanning), μ (pressure scanning) or ℓ (gap scanning). Both tilt and pressure scanning suffer from serious drawbacks which limit their dynamic range. With the advent of servo-controlled, capacitance micrometry, the performance of gap scanning etalons surpasses other techniques. These employ piezoelectric transducers that undergo dimensional changes in an applied electric field or develop an electric field when strained mechanically. Queensgate Instruments Ltd have shown that it is possible to maintain plate parallelism to an accuracy of $\lambda/200$ while continuously scanning over several adjacent orders.

Fabry–Perot filters have been made with 15 cm apertures and physical scan ranges up to 3 cm. The etalon is ultimately limited by the finite coating thickness between the mirrors, so it really only achieves the lowest interference orders ($m < 5$) at infrared wavelengths.

Solid etalon filter. These are single-cavity Fabry–Perot devices with a transparent piezoelectric spacer, e.g. lithium niobate. The thickness and, to a lesser extent, refractive index can be modified by a voltage applied to both faces. For low-voltage systems, tilt and temperature can be used to fine tune the bandpass. High-quality spacers with thicknesses less than a few hundred microns are difficult to manufacture, so that etalon filters are normally operated at high orders of interference. The largest devices we have seen are 5 cm in clear aperture.

Michelson filter. In the Fourier transform or Michelson filter, the collimated beam is split into two paths at the front surface of the beam-splitter. The separate beams then undergo different path lengths by reflections off separate mirrors before being imaged by the camera lens at the detector. The device shown in figure 2 uses only 50% of the available light. As Maillard has demonstrated at the CANADA–FRANCE–HAWAII TELESCOPE, it is possible to recover this light but the layout is more involved.

The output signal is a function of path difference between the mirrors. At zero path difference (or arm displacement), the waves for all frequencies interact coherently. As the movable mirror is scanned, each input wavelength generates a series of transmission maxima. Commercially available devices usually allow the mirror to be scanned continuously at constant speed or to be stepped at equal increments. At a sufficiently large arm displacement, the beams lose their mutual coherence.

The filter is scanned from zero path length ($x = y = 0$) to a maximum path length $y = L$ set by twice the maximum mirror spacing ($x = L/2$). The superposition of two coherent beams with amplitudes b_1 and b_2 in complex notation is $b_1 + b_2 e^{i2\pi\nu y}$ where y is the total path difference

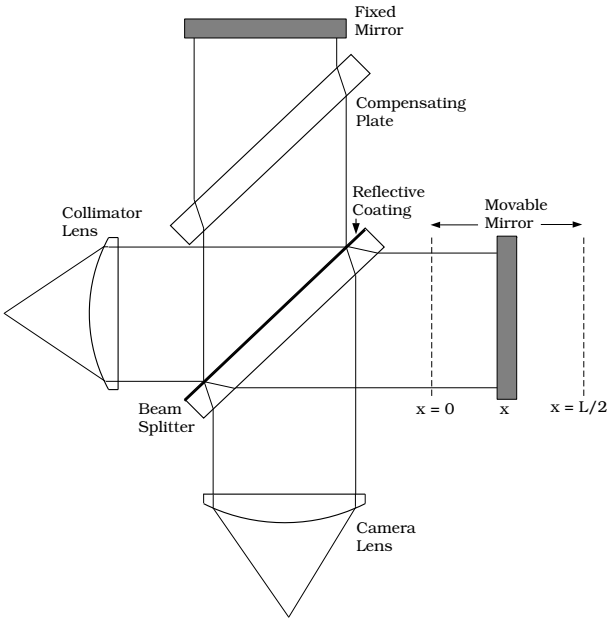

Figure 2. Schematic of a two-beam Michelson (Fourier transform) interferometer.

and ν is the wavenumber. If the light rays have the same intensity, the combined intensity is $4b^2 \cos^2 \pi \nu y$, where $b = b_1 = b_2$. The combined beams generate a series of intensity fringes at the detector. If it was possible to scan over an infinite mirror spacing at infinitesimally small spacings of the mirror, the superposition would be represented by an ideal Fourier transform pair, such that

$$b(y) = \int_{-\infty}^{\infty} B(\nu)(1 + \cos 2\pi \nu y)\, \mathrm{d}\nu \tag{4}$$

$$B(\nu) = \int_{-\infty}^{\infty} b(y)(1 + \cos 2\pi \nu y)\, \mathrm{d}y \tag{5}$$

where $b(y)$ is the output signal as a function of path length y and $B(\nu)$ is the spectrum we wish to determine. $B(\nu)$ and $b(y)$ are both undefined for $\nu < 0$ and $y < 0$: we include the negative limits for convenience. Note that

$$b(y) - \tfrac{1}{2}b(0) = \int_{-\infty}^{\infty} B(\nu) \cos 2\pi \nu y\, \mathrm{d}\nu \tag{6}$$

$$B(\nu) = \int_{-\infty}^{\infty} [b(y) - \tfrac{1}{2}b(0)] \cos 2\pi \nu y\, \mathrm{d}y \tag{7}$$

The quantity $b(y) - \frac{1}{2}b(0)$ is usually referred to as the interferogram although this term is sometimes used for $b(y)$. The spectrum $B(\nu)$ is normally computed using widely available fast Fourier transform methods. The construction of a Michelson filter is a major optomechanical challenge. The ideal Fourier transform pair is never realized in practice. However, the Michelson filter probably comes closest to achieving the goal of an ideal tunable filter.

The Michelson does not suffer the coating thickness problems of the Fabry–Perot filter, and therefore reaches the lowest orders even at optical wavelengths.

Grating filters

Resonant grating filter. These novel filters are inspired by the diffractive colors in many insects and constitute dielectric gratings with three-dimensional, sub-micron microstructure. The zeroth-order reflection exhibits a broad to intermediate bandwidth ($\mathcal{R} \sim 20$), is highly polarized and maintains useful efficiency over a $\pm 30^\circ$ tilt (or rotation) range. Gale (1998) presents one grating design that produces a roughly self-similar bandpass from 450 to 850 nm over this tilt range. Grating filters, and their close relatives, evanescent gratings, show great promise but most have yet to leave the drawing board. However, since much of the research is driven by bank note security, we expect rapid progress. Volume phase holographic gratings—in reflection—can produce a highly efficient grating filter through Bragg diffraction.

Acousto-optic filter (AOTF). These are electronically tunable filters that make use of acousto-optic (either collinear, or more usefully, non-collinear) diffraction in an optically anisotropic medium. AOTFs are formed by bonding piezoelectric transducers such as lithium niobate to an anisotropic birefringent medium. The medium has traditionally been a crystal, but polymers have been developed recently with variable and controllable birefringence. When the transducers are excited to 10–250 MHz (radio) frequencies, the ultrasonic waves vibrate the crystal lattice to form a moving phase pattern that acts as a diffraction grating. The diffraction angle (and therefore wavelength) can be tuned by changing the radio frequency. These devices are often water cooled to assist the thermal dissipation, although this is less important in the UV where AOTFs are particularly useful. The largest devices are 2.5 cm in diameter since it proves to be difficult to maintain a uniform acoustic standing wave over larger areas. An additional problem is the 15 μm structure in the $LiNO_2$ crystal which is not always optimal for good image quality. However, the acceptance angle of the AOTF is generally larger than that of the Fabry–Perot.

Birefringent filters

The underlying principle of the birefringent filter is that light originating in a single polarization state can be made to interfere with itself. An optically anisotropic, birefringent medium can be used to produce a relative delay between ordinary and extraordinary rays aligned along the fast and slow axes of the crystal. (A birefringent medium has two different refractive indices, depending on the plane of light propagation through the medium.) Title and collaborators have discussed at length the relative merits of different types of birefringent filters. The filters are characterized by a series of perfect polarizers (Lyot filter), partial polarizers, or only an entrance and an exit polarizer (Šolc filter). The highly anisotropic

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

off-axis behavior of uniaxial crystals give birefringent filters a major advantage. Their solid acceptance angle is 1–2 orders of magnitude larger than is possible with interference filters although this is partly offset by half the light being lost at the entrance polarizer.

Lyot filter. This is conceptually the easiest to understand and forms the basis for many variants. The entrance polarizer is oriented 45° to the fast and slow axes so that the linearly polarized, ordinary and extraordinary rays have equal intensity. The time delay through a crystal of thickness d of one ray with respect to the other is simply $d\Delta\mu/c$ where $\Delta\mu$ is the difference in refractive index between the fast and slow axes. The combined beam emerging from the exit polarizer shows intensity variations described by $I^2\cos(2\pi d\Delta\mu/\lambda)$ where I is the wave amplitude. As originally illustrated by LYOT (see figure 3), we can isolate an arbitrarily narrow spectral bandpass by placing a number of birefringent crystals in sequence where each element is half the thickness of the preceding crystal. This also requires the use of a polarizer between each crystal so that the exit polarizer for any element serves as the entrance polarizer for the next. The resolution of the instrument is dictated by the thickness of the thinnest element. With quarter-wave plates placed between each of the retarder elements, λ can be tuned over a wide spectral range by rotating the crystal elements. However, to retain the transmissions in phase requires that each crystal element be rotated about the optical axis by half the angle of the preceding thicker crystal.

Woodgate (NASA Goddard Space Flight Center) has made a Lyot filter utilizing eight quartz retarders with a 10 cm entrance window. The retarders, each of which is sandwiched with half-wave and quarter-wave plates in addition to the polarizers, are rotated independently with stepping motors under computer control. They achieve a bandpass of 0.4–0.8 nm tunable over half the optical wavelength range (350–700 nm).

Šolc filter. These highly non-intuitive filters use only two polarizers and a chain of identical retarders with varying position angles (Evans 1958). There are folded (zigzag) and fanned designs with the former having the better performance. Title has made a tunable Šolc filter with 7 cm clear aperture. It has the extraordinary capability of tuning the spectral profile: an n-element Šolc filter can have a profile that is determined by n Fourier coefficients. The same can be achieved with polarizing filters by proper choice of crystal lengths.

Liquid crystal filter (LCTF). These are rapid switching, electronically tuned devices which employ either ferroelectric or nematic liquid crystals. The more commonly used nematic LCTF (Morris *et al* 1994) comprises a series of liquid crystal elements whose thicknesses are cascaded in the same way as the Lyot filter. However, the tuning is achieved by electronically rotating the crystal axes of the liquid crystal waveplate. When no voltage is applied, the retardance is at a maximum; at large applied voltages, the retardance reaches a minimum. The retardance can be tuned continuously to allow the wavelength to be tuned.

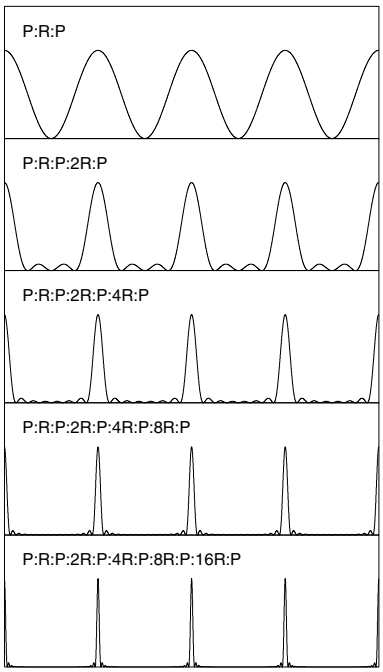

Figure 3. The transmission profile of a simple Lyot cascade with (top to bottom) 1, 2, 3, 4 and 5 stages. The thinnest element has retardance R and the following elements have thicknesses which are multiples of this element. The polaroids P are aligned with each other and oriented at 45° to the retarders.

Liquid crystal filters are now commercially available from Cambridge Research & Instrumentation, Inc. The biggest device we have seen has a clear aperture of 4 cm, requires about 5 V to scan a single order of interference and appears to have good image quality. The tunable band for a single-stage device is about $\mathcal{R} \sim 5$ but can be tuned over the optical window. The peak transmissions are 30% or less.

Differential imaging

There are many important reasons for pursuing tunable filter imaging, as demonstrated by the TTF since the mid-1990s at the ANGLO-AUSTRALIAN 3.9 m TELESCOPE and the William Herschel 4.2 m telescope (see ISAAC NEWTON GROUP OF TELESCOPES). Conventional imaging has a major limitation in that images are taken sequentially which is not ideal at even the best sites. Even small detector, instrument or atmospheric variations lead to systematic error between images. A better approach is a multiband camera so that different bands are observed in parallel. However, even this is not ideal in that the optical path is different for each filter. A tunable filter provides a powerful alternative since band switching can be linked to charge shuffling with the CCD. This is a truly differential

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

technique which leads to much smaller systematic errors than is possible with conventional imaging.

Wide-field imaging

Few telescopes offer more than a wide-field imager at prime focus simply because it is very difficult to exploit the fast beam spectroscopically (see WIDEFIELD CCD IMAGERS). Spectral passbands are degraded in converging beams which is unfortunate as the widest fields are achieved at the fastest f ratios. The wide-field expanded Lyot filter is (almost) the last word in exploiting the widest possible field with a given telescope. Remarkably, beams as fast as $f/2$ can be compensated with crossed birefringent elements, in concert with half-wave plates, such that even a constant sub-ångström bandpass is possible over a degree-sized field. This opens up many new astronomical programs, e.g. Lyot filters can be vastly more efficient for GALAXY REDSHIFT SURVEYS of galaxies (e.g. high-redshift clusters) compared with existing multi-aperture SPECTROGRAPHS. To our knowledge, a wide-angle Šolc filter using half-wave plates has not been attempted although it is entirely feasible.

Tunguska Event

An explosion in mid-air on the morning of 30 June 1908 over a remote forest region of eastern Siberia near the Podkamennaya Tunguska river that caused widespread devastation. The few eyewitnesses reported a fireball as bright as the Sun. The explosion itself was heard up to 1000 km away, and sent pressure waves twice around the planet that were recorded by seismographic stations. The forest canopy burned for over two days. Trees and reindeer in the central 1000 km^2 area beneath the blast were incinerated, and up to 50 km away trees were felled by the shock wave. Dust from the explosion blanketed the area and was carried round the world by atmospheric currents, causing colorful sunsets. It was 20 years before the first scientific research team, led by Leonid Kulik, reached the area. They found no main impact crater or meteoritic fragments; later expeditions, however, recovered dust particles preserved in tree resin and found them to be consistent in composition with stony meteorites. It seems, then, that a stony meteorite with a diameter of about 50 m fragmented and vaporized at an altitude of about 8 km.

Tuorla Observatory

Founded in 1952, Tuorla Observatory lies at an altitude of 53 m and is located 12 km from Turku in Finland. It is the site of the headquarters of the NORDIC OPTICAL TELESCOPE.

Early research activities included setting up a geodetic triangulation network for measuring distances, optical work, zenith tube studies of polar motion, detections and orbital calculations of minor planets and comets. Today, research includes active galaxies and stellar dynamics.

The main instrument is a 1 m Dall–Kirkham reflector, used for CCD photometry of quasars. Other instruments include a 0.7 m Schmidt telescope, a 0.6 m Ritchey–Chrétien telescope and a 0.39 m zenith telescope. However, the observatory's most important observations are made abroad, especially at the Nordic Optical Telescope.

During the 1974 nationalization of Turku University, the observatory lost its independent status and became part of the Department of Physical Sciences. In 1989 the observatory buildings were enlarged, and in 1991 Tuorla once again became independent under the jurisdiction of the University.

Tuorla also contributes to the VLBI facility at the Metsähovi Radio Research Station of the Technical University of Helsinki.

Twilight Glow

The scattered light before sunrise and after sunset that partially illuminates the sky. This relatively steady glow is part of the overall phenomenon called airglow—the light produced and emitted by the Earth's own atmosphere. The spectrum ranges from 100 nm to 22.5 μm.

Tycho (Crater)

A prominent young lunar crater in the Moon's southern uplands, and the hub of the Moon's most striking ray system. Its diameter is 102 km, and it is centered at 43.4 °S, 11.1 °W; it is named after the astronomer Tycho Brahe. The crater is one of the youngest features of the Moon, perhaps just 100 million years old. Its ray system extends for up to 1500 km in all directions, and is most prominent at full moon, when the fresh ejecta from which it is composed reflect sunlight back toward the Earth, and the rays are seen to extend over much of the Moon's nearside. The crater itself has terraced walls, caused by partial slumping of sections of the inner rim, which rise to 4.5 km, and a pronounced central peak. For over 80 km beyond the rim there is a continuous deposit of ejecta (an ejecta blanket) in all directions. Rock melted by the impact flowed down the outside to solidify in pools, and down the inside of the rim in rivulets toward the crater floor. Material ejected on higher trajectories produced the rays and also many secondary craters.

Tycho Brahe (1546–1601)

Much of Tycho (Latinized from Tyge, pronounced 'Teeko') Brahe's accomplishment was made possible by the unique circumstances of his birth and upbringing. He was born on 14 December 1546 to Otte Brahe and Beate Bille, and thus into the highest stratum of Danish society, a powerful oligarchy of aristocratic families. Strangely, he was kidnapped by his uncle before he was two years old, and raised as the foster son of Jørgen Brahe and Inger Oxe. The tradition of the Oxe family seems to have influenced Tycho to cultivate learning rather than the aristocratic martial pursuits of his birth brothers.

After attending the University of Copenhagen (1559–1561), Tycho proceeded to the Lutheran universities of Germany, primarily Leipzig (1562–1565) and Rostock (1566–1567), ostensibly pursuing humanistic and legal studies but actually becoming more and more interested in alchemy and astronomy. It was at Rostock in December 1566 that Tycho lost the bridge of his nose in a duel with another Danish noble student. Thereafter he wore a prosthesis of gold and silver blended to a flesh colour. Tycho traveled widely in Germany and Switzerland during the late 1560s, finding congenial intellectual circles in Basel and Augsburg.

Recalled by his ailing father, Tycho returned to Denmark at the end of 1570 and settled at his ancestral home Kundstrup Manor in Skaane (now southern Sweden) and then at nearby Herrevad Abbey. Around 1571, he fell in love with Kirsten Jørgensdatter, with whom he remained for the rest of his life, though they could never marry because she was a commoner. After publishing a book on the nova of 1572 and lecturing informally at the University of Copenhagen in the autumn of 1574, Tycho was on the point of emigrating from Denmark better to pursue his intellectual interests and for the sake of his common-law wife and family.

Having heard of Tycho's plans, on 11 February 1576 King Frederick II offered Tycho the isolated island of Hven in the strait off Copenhagen and the funds to found and maintain an observatory. That summer Tycho began the construction of a castle/scientific institution, which he named Uraniborg, Urania's castle. From the alchemical furnaces in the basement, to the high observing decks with their removable roofs, to the library with its great celestial globe, to the garret rooms for students and assistants, every element of the structure was devoted to Tycho's dual interests of astronomy and alchemy. His facilities also included an instrument shop and a printing press and paper mill for disseminating his findings. With the problems of wind and vibration atop Uraniborg as well as the increasing scale of Tycho's instruments, he subsequently founded a nearby subterranean observatory called Stjerneborg, the castle of the stars, which housed his largest and most sophisticated instruments.

Tycho's whole enterprise on Hven was underwritten handsomely by King Frederick. After his death in 1588 during the minority of King Christian IV, when the country was run a council of regents filled with Tycho's relatives and friends, the generous funding continued. Tycho's heirs later estimated that he spent 100 000 florins over his lifetime amassing his observations. However, if Tycho was adept at soliciting patronage, he was not conscientious about fulfilling his modest responsibilities. He was therefore an easy target when King Christian came of age in 1596 intent on recapturing control over crown funds. The sudden collapse of Tycho's royal funding and persistent fears about transfering wealth to his family, who could not inherit because they were not noble, led Tycho to close Uraniborg and withdraw to northern Germany in 1597.

By the middle of 1599, Tycho had secured an even greater patron, the eccentric Holy Roman Emperor Rudolf II. Offered his choice of castles, Tycho selected Benatky Castle in the countryside north of Prague, where he began trying to construct a 'New Uraniborg'. However, by early 1601, the emperor had him move into the city in order to be more accessible for astrological advice. Tycho's research and publishing programs never recovered from the frequent moves of his last years. Finally, after drinking overgenerously at a party and not excusing himself from the table for some reason of etiquette, he suffered a fatal bladder complication, and died on 24 October 1601.

Tycho's dying words, 'Let me not seem to have lived in vain', were inscribed on the final page of his observing log by an assistant, who by virtue of the attrition in Tycho's staff during his final years unexpectedly rose to become his successor. His name was Johannes KEPLER.

The nova of 1572 and the comet of 1577

The two most celebrated of Tycho's observational findings involved transient phenomena, the nova of 1572 and the comet of 1577. Ironically, both occurred before the golden age of observing at Uraniborg, and were observed with Tycho's more primitive instruments. However, both had profound cosmological implications.

On 11 November 1572, Tycho noticed a new, intensely bright star in CASSIOPEIA. The new star (*nova stella*), now technically known as a SUPERNOVA, was bright enough to be visible during the daytime. Observing it with an astronomical radius and his early wooden half-sextant, Tycho discovered something of extreme importance: it displayed no diurnal parallax whatsoever, and therefore lay beyond the sphere of the Moon (a rather solid conclusion because the Moon itself displays 1° of diurnal parallax). Tycho published his findings in a modest book entitled *De nova stella* (1573).

According to Aristotelian cosmology, the supralunar realm consisted entirely of the fifth element, ETHER, which by its nature was incapable of change. However, the star had come into being and passed away. This single inconsistency was not itself enough to bring down a cosmological system that stood near the center of Western philosophy (Tycho himself regarded the nova as a special creation of God), but it became an important element in the reconsideration of Aristotelian cosmology that took place during the latter half of the 16th century.

Tycho was privileged to observe not only a supernova but also one of the most spectacular comets in recorded history. He first sighted it at dusk on 13 November 1577 while catching fish for dinner from one of his ponds on Hven. Although Uraniborg was only under construction, Tycho managed to observe the comet with his new medium brass quadrant and his steel sextant. Because of the comet's movement, the reduction of the observations was more complex, but Tycho was able to plot its motion both in equatorial and ecliptic coordinates. He eventually concluded from the comet's motion and its imperceptibly small diurnal parallax that the comet was moving through space somewhere near the sphere of Venus.

This was a result of great significance, for by the late 16th century many had come to the conclusion that Aristotle's ether spheres were to be understood in terms of hard, impenetrable, crystalline spheres. According to Tycho, the comet had moved through those spheres, and he later claimed that he had shown that those spheres had no reality. His treatise on the nova having been overwhelmed by a mass of hysterical amateur literature interpreting its meaning, Tycho resolved to wait to publish until he could collect and rebut the literature generated by the comet of 1577.

The Tychonic system

Ever since the publication of NICOLAUS COPERNICUS's *De revolutionibus* (1543) astronomers were in a quandary. On the one hand, they admired Copernicus's elegant mathematical planetary theories, which had done away with the physical non-uniformity of motion inherent in Ptolemy's equant. On the other hand, the motion of the Earth in the heliocentric system was regarded by most as 'offending the principles of physics and of Holy Scripture', as Tycho put it. A few pursued the idea of transforming the COPERNICAN SYSTEM to keep the Earth at rest and to put into motion the Sun with the planets circling around it. However, the relative distances of the Earth and Mars in the Copernican system proved a stumbling block, for the transformed system required a problematic intersection of the Sun's and Mars' spheres.

The available evidence suggests that Tycho began developing his TYCHONIC SYSTEM only around 1584. He was at that time in the midst of an observational campaign to detect by means of Mars' diurnal parallax near opposition whether it approached closer to the Earth than the Sun. Since Mars does so in the Copernican system but not in the PTOLEMAIC SYSTEM, the observation promised the ability to decide observationally between the two cosmological systems.

With the evidence of Mars' parallax ambiguous but suggestive, and the evidence from the comet of 1577 for the incorporeality of the celestial spheres, Tycho was in the position to propose his new cosmological system. In the Tychonic geoheliocentric system, the Earth is at rest in the center of the universe while the Sun, with the planets orbiting around it, orbits the Earth. Tycho inserted his account of the new system as an initially unplanned chapter 8 in his book on the comet of 1577, *De mundi aetherei recentioribus phaenomenis* (1588), published as the second volume of Tycho's planned three-volume *Astronomiae instauratæ progymnasmata* (the first volume of which finally appeared posthumously in 1602).

Tycho's compromise cosmology was widely adopted and taught, giving rise to vociferous priority claims, especially against Nicholas Reimers Ursus, who published a similar system as his own later in the same year. (In Tycho's defense, it should be noted that an essential element of the system was his resolution of the problematic intersection of the Sun's and Mars' spheres.) The Tychonic system remained a serious alternative to the Copernican system well into the 17th century, long after the demise of the Ptolemaic.

Instrument design

Tycho improved instrument design in every respect, from the details of sights and divisions, to materials, to the type of instruments he made. He had his best instruments made during the 1580s, but even before the founding of Uraniborg Tycho had arrived at some of his most fundamental innovations.

Although Tycho eventually developed techniques to harness the power of instruments of great size, the precision of his instruments depended primarily on his innovative sights and divisions. He instituted the use of linear transversals applied to his circular scales on an experimental basis on his medium brass quadrant (ca 1577) and steel sextant (ca 1574), and then used them on all subsequent instruments. Although criticized by some for not being mathematically rigorous, Tycho demonstrated a maximum geometrical error of linear transversals to be 3″, far too small to be detectable. On his larger instruments, the transversals were capable of resolving angles as small as 20 arcsec.

Traditional pinhole sights were a far greater source of error. Since the front sight had to be at least big enough to sight the object through, it necessarily introduced an error of 5–10′. Tycho's innovative twin-slit sights did away with error in the front sight by replacing it with an obstruction. If an object could be sighted on either side of the obstruction through two parallel slits at the rear, it would be correctly oriented to the limit of the error introduced by the finite width of the rear sights, which could be progressively narrowed. These too were first introduced on the medium brass quadrant. The only significant modification of the system was the substitution of a cylindrical obstruction at the front, which would appear as an identical rectangular obstruction from any location along the arc, a very useful feature especially for his later quadrants and sextants, where two observers used a single post at the apex as a shared front sight.

Tycho experimented with a wide variety of designs but his working instruments fell into three families. Greatest in number were the azimuth quadrants, a design series that culminated in the revolving azimuth quadrant

(1586) and the great steel sextant (1588) in Stjerneborg. Tycho had less success with another traditional class of instruments, the armillary family. Although armillaries offered the advantage of being able to measure directly in equatorial or ecliptic coordinates, with their many rings they were fussy to make and use. Tycho was only able to become satisfied with them by progressively simplifying the design, and finally abandoning the ring arrangement altogether. His great equatorial armillary (1585) in Stjerneborg consisted only of a very large declination circle pivoting around a polar axis, with differences in right ascension being measured by means of a large fixed equatorial arc (see ARMILLARY SPHERE).

Tycho's signature instrument—the one for which he most vigorously claimed priority—was his astronomical sextant, which reached its mature form in the trigonical sextant (1582). It was explicitly designed as a replacement for the unsatisfactory traditional astronomical radius, or Jacob's staff, for the purpose of measuring angular separation in any plane. Because Tycho never developed satisfactorily accurate clocks, he did not measure positions in absolute equatorial coordinates but determined positions by triangulating from the positions of reference stars, for which the sextant was essential.

Various analyses have been made of the accuracy of Tycho's observations, which he acknowledged increased over his lifetime. It is safest to say that during his mature observing career, he consistently achieved his stated goal of 1′ accuracy.

Planetary theory

Tycho planned a restoration of astronomy based on a comprehensive collection of accurate observations, but died before the task was complete. The only theories he left in a reasonably satisfactory state were a solar and a lunar theory.

His solar theory followed a long tradition begun by HIPPARCHUS in consisting of a circular orbit with a simple, unbisected eccentrity. His major contribution was a thorough redetermination of the parameters; his final form had an apogee of $95\frac{1}{2}^\circ$ and an eccentricity of 0.0358 (equivalent to a post-Keplerian eccentricity of 0.0179), with an obliquity of $23^\circ\,31'\,30''$. The only value he did not reestablish was the erroneously large value of 3′ for solar parallax from antiquity, which played havoc with his solar theory. However, the results were tempered by Tycho's pioneering systematic attention to atmospheric refraction, with his exaggerated solar refraction table essentially canceling out the spurious value of solar parallax.

Most of the work on the lunar theory was undertaken by Tycho's most capable assistant CHRISTIAN SEVERIN (1562–1647). Too complex to be described here, the work was notable for Tycho's discovery, based on his extensive observations, of two new lunar anomalies, the variation and the annual equation.

Tycho put off the production of finished theories for the rest of the planets (the subject of the never-completed third volume of the *Progymnasmata*) until his Prague period, when first Longomontanus and then Kepler was assigned to the theory of Mars. He died before any were reduced to a finished form. Kepler would not produce a complete set of planetary tables based on Tycho's observations until long after Tycho's death. Although Kepler had in the meantime wrought decisive changes to astronomical theory, his *Rudolphine Tables* (1627) still listed Tycho as first author.

Tycho Star Catalogs: The 2.5 Million Brightest Stars

The knowledge of positions, motions in the sky, brightnesses and colors of the brightest stars is the basis for investigations in nearly all branches of astronomy and astrophysics. The HIPPARCOS space astronomy mission launched in August 1989 and operating until mid-1993 was dedicated to obtain such information. The measurements by the Tycho experiment onboard the satellite have increased the previous knowledge of this kind by several orders of magnitude. The first Tycho Catalog (Tycho-1) published in 1997 gives the positions and magnitudes in two color bands for one million stars.

The motion in the sky (PROPER MOTION) could not be accurately derived from the change of star position during the short time interval of three years of the Hipparcos mission. The positions in the one hundred year old Astrographic Catalog have therefore been combined with the Tycho-1 positions to produce accurate proper motions for all stars, as published in 1998.

A second reduction of the Tycho observations has been carried out with more powerful modern computers, resulting in the Tycho-2 Catalog to be published in 2000. It will contain accurate information for 2.5 million stars, including proper motions based on the positions in the Astrographic Catalog and 145 other ground-based catalogs.

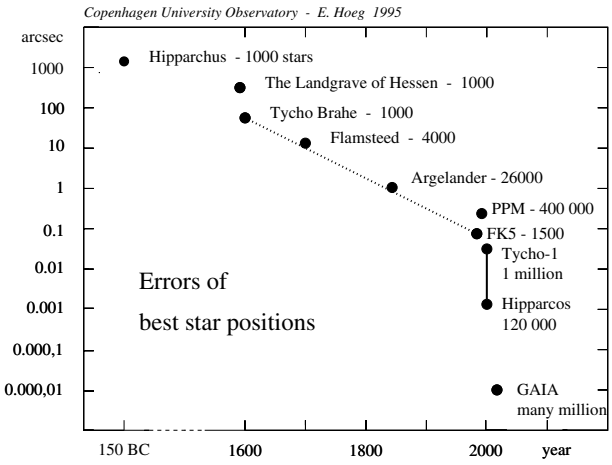

Figure 1. Errors of star positions in the most accurate catalogs. Tycho Brahe achieved a jump in accuracy. After four centuries with more gradual improvements another leap was obtained with the ESA satellite giving the Hipparcos and Tycho Catalogs containing a total of one million stars. Further improvement is expected with the planned ESA satellite GAIA for many more stars; about 40 million stars with 10 microarcsecond and 1 billion with better than 150 microarcsecond accuracy.

Catalogs of star positions

Catalogs of star positions and brightnesses (magnitudes) in the optical range are prerequisites for the study of almost all celestial objects. Given the position on the sky the stars are identified as individual objects, and can then in principle be observed by any kind of telescope for electromagnetic radiation, from radio waves over infrared and optical to x-ray and gamma-ray, in order to assess the physical nature of the object. The brightest stars in the optical range encompass a wide range of astronomical objects, from the compact white dwarfs to red giants and variable stars. The positions of other fainter objects such as galaxies and quasars are derived from special observations, relative to the positions of brighter reference stars.

The first prominent catalog in modern time was produced by TYCHO BRAHE in the late 16th century and contained about 1000 stars with an unprecedented accuracy of position. The accuracy of measurement was gradually improved as the technology became available, and the number of stars could be increased. The most accurate primary instrument (before Hipparcos) for ASTROMETRY, or positional astronomy, was the meridian circle, a telescope mounted on an east–west axis and observing the stars as they cross the meridian, one star at a time. This resulted in catalogs of fairly bright reference stars.

A large number of fainter stars could then be tied to these reference stars by means of exposures on photographic plates covering the whole sky. The first photographic survey of the sky was one of the largest international cooperations in astronomy carried out mainly from 1891 to 1920. It resulted in the Astrographic Catalog containing 8.6 million positions of about 4.5 million stars. But this catalog made very little scientific impact for nearly a century for two reasons. Firstly, the Astrographic Catalog positions were only available in 254 printed volumes, until a few years ago when they were painstakingly key-punched and thus put on machine-readable form. Secondly, an accurate net of reference stars only became available through the Hipparcos Catalog.

During the 20th century great efforts were expended by astrometrists in the production of hundreds of position catalogs both by meridian circles and photographically in order to satisfy the needs of astronomy. In the 1990s the scene changed with the completion of the Hipparcos satellite mission. A larger and more accurate reference system became available, and the Tycho Catalog contained positions of one million stars in a second observation epoch nearly 100 years after the Astrographic Catalog so that accurate proper motions could be derived from a combination of these two catalogs.

Tycho observations

The European Space Agency (ESA) satellite Hipparcos carried out astrometric and photometric observations from 1989 to 1993 resulting in the HIPPARCOS AND TYCHO CATALOGS. The satellite obtained very high accuracy astrometry for 120 000 stars, the Hipparcos Catalog. These stars plus an additional 935 000 stars were detected and measured with

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

a more modest accuracy by the satellite's star mapper slits resulting in the Tycho Catalog, hereafter abbreviated to Tycho-1. This catalog contains astrometry and two-color photometry (B_T, V_T) for all stars. The two color bands in the blue and visual parts of the spectrum are close to the so-called Johnson B and V frequently used in astronomy.

The star mapper slits were placed in the focal plane of the Hipparcos telescope, beside the Hipparcos main field. The light passing through the slits was measured by simultaneous photon counting with two photomultipliers, one in each of the color bands. The original Tycho reduction was done by detecting a significant signal whenever the stars of an input catalog crossed the slit system. The improvement in the new reduction is achieved by superimposing the photons that were counted during all the about 130 observations per star obtained during the mission.

Table 1. Principal observational characteristics of the Tycho-2 Catalog. ICRS is the International Celestial Reference System. By means of proper motions the observed positions are transferred to the year J2000.0, the epoch of the catalog. The median values of standard errors are given. Unit: mas=milliarcsecond.

Observation period of satellite	1989.85–1993.21
Mean observation epoch	∼J1991.25
Epoch of Tycho-2 Catalog	J2000.0
Reference system	ICRS
coincidence with ICRS†	±0.6 mas
deviation from inertial†	±0.25 mas/yr
Number of entries	2540 000
Astrometric standard errors	
V_T < 9 mag, positions	9 mas
all stars, positions	60 mas
all stars, proper motions	2.5 mas/yr
Photometric errors on V_T	
V_T < 9 mag	0.012 mag
all stars	0.09 mag
Sky density‡	∼60 deg^{-2}
Limiting magnitude	$V \sim 12.5$ mag
Completeness to ∼90 %	$V \sim 11.5$ mag
Completeness to ∼99 %	$V \sim 11.0$ mag
Total number of observations	$\sim 300 \times 10^6$

† per axis for all three axes.
‡ depending on galactic latitude.

In the original Tycho-1 project astrometric and photometric data for 1052 000 stars to a limit of V_T =11.5 mag were derived. The brightest 99% of the stars obtained magnitudes in two passbands B_T and V_T. A precision (median internal standard error) of 7 mas was achieved in astrometry (positions, annual proper motions and parallaxes) for stars with V_T < 9 mag, and 25 mas for all stars. The median precision in photometry was 0.012 mag for V_T of the bright stars and 0.06 mag for the whole catalog. Double stars with sufficient brightness and separation larger than 2 arcsec were resolved. The processing was based on predicted star transits using a dedicated 'Tycho Input Catalog', compiled from existing star catalogs. The data treatment was carried out by the Tycho Data Analysis Consortium, using satellite attitude

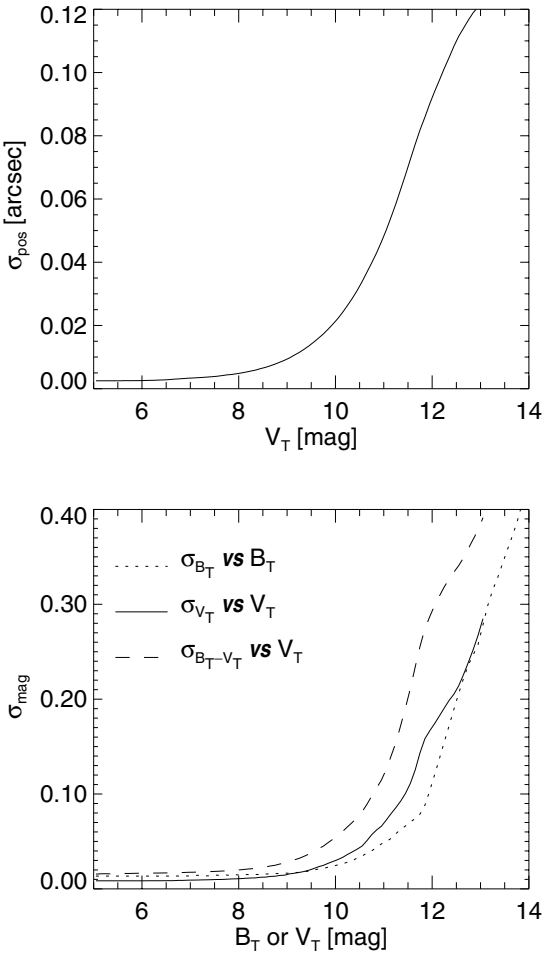

Figure 2. The Tycho-2 Catalog: standard errors of position components, magnitudes and color indices.

information, and photometric standard stars from the Hipparcos data reduction consortia.

The Tycho-2 catalog

The processing of Tycho observations for the first Tycho Catalog was based on detections of each transit above a certain signal-to-noise ratio (1.5 or 1.8).

For the second Tycho Catalog a much better solution, namely *a photon superposition for the whole mission*, has been realized. This idea was already suggested in 1982 when the Tycho project was proposed to the EUROPEAN SPACE AGENCY (ESA), but had to be abandoned at that time in favor of the more modest approach. The photon superposition gives better astrometric and photometric values for the fainter half of the original one million stars. A major reason for the improvement is that an astrometric estimation based on very few photons does not achieve the so-called CRAMÉR–RAO LIMIT. An estimation based on all photons from many transits comes much closer to that limit. Furthermore, many transits of the faint stars were below the limit

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

of signal-to-noise ratio for the detection and were thus completely lost.

The Tycho-2 Catalog (see table 1 and figure 2) contains astrometry and photometry for 2.5 times as many stars as the Tycho-1.

Future developments

In the Tycho-2 processing, emphasis was placed on the optimal treatment of the bulk of stars which are single, but an effort was also made to detect and measure double stars. This resulted in about 8000 pairs with separations down to 0.8 arcsec, while the resolution limit in Tycho-1 was about 2 arcsec. The processing also gave insight into still unexploited possibilities. A special double star processing, where the Tycho-2 results are used as input, will give detection and measurement of closer pairs and of presently unknown fainter companions of many thousands of stars. It has also become clear that a special variable star processing should be applied because thousands of new variables can be detected, many more than can be detected from the published photometric annexes to the Tycho-1 Catalog. These surveys of double and variable stars would be complete and uniform over the sky to an extent which could only be superseded by a future astrometric satellite.

Tycho's Star

A supernova remnant in Cassiopeia, 7.7° north of α Cas, which suddenly appeared as a brilliant naked-eye star in November 1572 and reached a maximum apparent magnitude of −3.5. Until its disappearance 16 months later, it was extensively studied by the Danish astronomer Tycho Brahe (1546–1601), who described its early appearance as follows: 'Initially, the new star was brighter than any other fixed star, including Sirius and Vega. It was even brighter than Jupiter.... It kept approximately the same brightness for almost the whole of November. On a clear day it could be seen at noon.' (*De Stella Nova*, 1573.)

In 1952 observations made by Robert Hanbury-Brown (b. 1916) at the Nuffield Radio Astronomy Laboratories, Jodrell Bank, identified the supernova location with the discrete radio source 3C 10 (also known as Cassiopeia B). Hanbury-Brown mapped the detailed structure of the radio source, following which Rudolph Minkowski (1895–1976) detected optical remnants with the 5 m (200 inch) Hale telescope at the Palomar Observatory, California. (This radio source should not be confused with the much stronger nearby source, Cassiopeia A, which is believed to be an ancient type II supernova remnant.) The remnant of Tycho's supernova has also been identified as a weak x-ray source.

The detailed records kept by Tycho Brahe enabled a light curve to be constructed which indicates that the object was a type I supernova. Recent measurements suggest that the remnant is probably between 8000 and 10 000 light-years distant, in which case it reached an absolute magnitude at maximum of about −16. This is equivalent to a luminosity approaching 250 million times that of the Sun.

At present the faint remnants of the expanding gas shell have a radius of 3.7′, equivalent to an actual diameter of between 17 and 22 light-years, and a rate of expansion of 6000–7500 km s^{-1}. This is the highest expansion rate deduced for any object, and is about ten times that of the Crab Nebula, also a young supernova remnant.

Tychonic System

The world system proposed in 1583 by the Danish astronomer Tycho Brahe (1546–1601). Unable to accept the Copernican doctrine that the Earth moves around the Sun, he put forward the view, later disproved by Kepler (1571–1630), that the planets move around the Sun, but the Sun and Moon move around the Earth. The theory explained the observed variations of the phases of Venus, for which the Ptolemaic system had no explanation.

U Gem Stars

U Geminorum (U Gem) is the prototype for one subclass of dwarf nova (DN) systems. U Gem stars, like other DNs, brighten by factors of hundreds to thousands, sometimes in just a few hours. The eruptions recur quasi-periodically on intervals of weeks to years, with durations from a few days to a few weeks. U Gem stars, like all cataclysmic variables, are BINARY STAR systems consisting of a low-mass RED DWARF star (the secondary) and a WHITE DWARF star (the primary). The red dwarf is losing mass to the white dwarf through the inner LAGRANGIAN POINT (L1). This gas forms an ACCRETION DISK surrounding the white dwarf. The disk is usually the major source of radiation in the system. Another source of light is a bright spot formed where the stream collides with the outer edge of the disk. The other two subclasses of DN are the Z Cam and SU UMa stars. The Z Cam stars have similar outburst patterns with the addition of occasional extended standstills about 0.7 mag below maximum brightness. The SU UMa stars sometimes have superoutbursts that are brighter and longer duration than an ordinary outburst.

White dwarfs are very small yet contain about one solar mass. So they have deep gravitational potential wells. In DN systems the matter streaming from the red dwarf star releases a large amount of gravitational potential energy. In fact, accretion energy is the dominant light source in these systems. The gas stream leaving the L1 point of the secondary star cannot fall toward the white dwarf directly. Because the stream material carries angular momentum from the orbital motion of the secondary star it follows a curved path around the white dwarf star. The stream material forms a flat accretion disk. Most of the continuum radiation from DNs originates in dense regions of the disk and the bright spot formed by the stream–disk impact. The emission lines are formed in the lower-density outer disk or in the disk's chromosphere and perhaps the stream–disk impact site. In systems where the orbital plane is seen nearly on edge, the emission line profiles are double peaked. This is because the profile is actually composed of two Doppler-shifted components originating from opposite sides of the rotating disk. The accretion disk is the source of the DN outbursts. This was demonstrated by photometric observations of Z Cha. This binary is an ECLIPSING BINARY system, and during outburst the eclipse became much deeper, indicating that the disk was the source of the eruption rather than the foreground red dwarf.

Most of what we know about the visual light curves of DNs comes from the monitoring done by groups of amateur astronomers such as The American Association of Variable Star Observers (AAVSO). For many stars these visual observations span decades. The light curves reveal several details. Even for the same DN, no two outburst light curves are exactly the same (figure 1). For some systems (e.g. U Gem and SS Cyg (SS CYGNI)) there is a bimodal distribution of outburst durations with a tendency for outburst to alternate between long and short

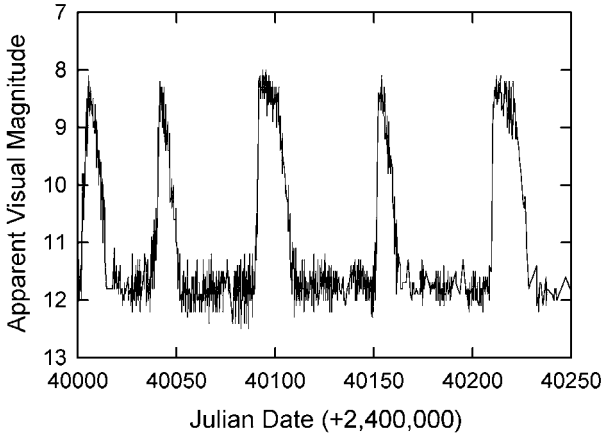

Figure 1. The U Gem star SS Cyg has an outburst about every 50 days. However, the duration, shape and amplitude of the outbursts are variable and mostly unpredictable. The light variations of SS Cyg are the best studied with the visual estimates made by members of the AAVSO. The figure above shows a small portion of their SS Cyg observations.

durations. Outbursts are classified, types A through D, based on their rise times to maximum light. Type A outbursts have rapid (∼2 days) rises. The system brightens at longer wavelengths first, with a delay of about a day between optical and the UV. In type B outbursts the rise of optical flux is a bit slower and nearly simultaneous at all wavelengths. There is a correlation (the Kukarkin–Parenago relationship) between outburst amplitude, A (in mag), and outburst duration, T' (in days),

$$A = 0.70\,(\pm 0.43) + (1.90 \pm 0.22)\log T'.$$

In quiescence the optical spectra are dominated by the hydrogen Balmer lines on a blue continuum. There are weak He I lines. Higher-excitation emission lines such as He II λ 4686 and the blend of C III and N III at λ 4650 are always very weak or absent. In the UV photospheric absorption lines of the white dwarf are visible, while lines from the secondary star can be seen in the IR for long-orbital-period systems. The light curve is often modulated on the orbital period owing to the changing aspect of the hot spot. In high-inclination systems this can produce a broad bump when the spot is seen face on, followed by an eclipse of the spot, disk and white dwarf by the secondary star. Analysis of eclipse light curves yields information about the size and location of these components.

In outburst the continuum brightens and the emission lines can become difficult or impossible to detect. They are often replaced by broad absorption lines. In the UV, low-inclination systems show blended emission and absorption lines (P Cygni profiles) that indicate mass outflow in a wind from the disk. In high-inclination systems the light curve bump produced by the bright spot remains at its quiescence level. This indicates that the outburst is not triggered by enhanced mass

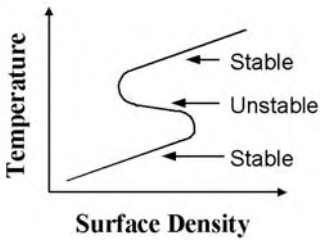

Figure 2. In the thermal instability model of DN outbursts there is a region in the disk with two stable temperature–surface density regimes. The mass transfer rate into the region determines where the region falls on the temperature–surface density curve. The outburst cycle is driven when the mass transfer rate into the region is too high for the lower branch and too low for the upper branch. The region cycles between the cooler region where mass transfer is less efficient (and mass accumulates) and the hotter upper branch with high transfer efficiency and larger mass inflow.

transfer from the secondary star. As time progresses the continuum fades, and the emission lines once again become prominent. However, the UV flux declines much more slowly, in some cases fading until the next outburst. This has been interpreted as the cooling of the white dwarf after the outburst.

Accretion disk models

In theoretical models the disk is treated as thin and flat with a constant flow of mass from the secondary star. The gravity of the disk itself is considered negligible compared with that of the white dwarf. The gas is assumed to move according to KEPLER'S LAWS. (This is not strictly true or there would be no inward motion and no mass accretion.) Gas particles above the plane of the disk feel a restoring force due to the vertical vector component of the central gravitational force. This is balanced by the local gas pressure, i.e. there is hydrostatic equilibrium in the 'vertical' direction. The surface density, Σ, at any point is defined as the amount of mass located beneath a square centimeter of surface, i.e.

$$\Sigma = 2\int \rho \, \mathrm{d}z$$

where ρ is the volume density and the z-axis is perpendicular to the disk plane. Because the disk particles orbit in a Keplerian fashion the rotation of the disk is differential. This results in shear between adjacent annuli producing a heating of the gas and an outward transport of orbital angular momentum. The net result is that most gas slowly spirals toward the white dwarf, releasing its gravitational potential energy as radiation. This process is determined by the viscosity of the gas. Unfortunately, we do not have a complete understanding of this viscosity. Convection may play an important role. In the disk models viscosity, ν, is treated as an adjustable parameter, α, i.e.

$$\nu = \alpha C_\mathrm{s} H$$

where C_s is the local sound speed and H is a density scale height. The disk models assume axial symmetry, that is for a given radius in the disk all physical parameters are the same. The disk models can predict the run of temperature and pressure throughout the disk. The emitted continuum spectrum is usually calculated by summing the BLACKBODY RADIATION from each annulus of the disk.

Outburst models

There are a variety of disk outburst models. The thermal instability model described below has been particularly successful. The following discussion is designed to give the reader a general idea of how this model works. References for further reading can be found in the bibliography.

The outbursts seen in DNs most likely result from increased mass flow through the accretion disk with accretion onto the white dwarf star. The rate of mass flow from the secondary star is usually assumed to be constant but there is a mechanism in the disk for temporarily storing matter. When the surface density reaches a critical value the viscosity increases and the matter is suddenly accreted onto the white dwarf. This produces the outburst. With time the surface density of the disk and the viscosity decrease and the mass build up in the disk begins anew.

Normally the temperature in a disk is expected to increase with surface density because higher surface densities lead to greater viscous heating. A plot of all possible combinations of local temperature versus surface density (T versus Σ) at a particular radius would give a positive-sloping curve. However, the outburst models require that at some location in the disk there are two possible values for temperature, for the same value of surface density. The outburst state corresponds to the high-temperature solution and the quiescent state to the low-temperature solution. The required curve in the temperature–surface density (T–Σ) plot is s shaped (figure 2). Only the upper and lower branches of this curve represent stable solutions for a disk. The outbursts are departures from thermal equilibrium.

For a disk to be in thermal equilibrium the temperature must return to its initial value despite small perturbations. Normally this is the case. For example, if the midplane temperature is slightly reduced for a time, the surface density would increase owing to a reduced efficiency of viscosity in transporting mass inward. The increased surface density results in increased viscous heating, which returns the temperature and the surface density to their initial values. This thermally stability is characterized by a positive slope of the T–Σ curve, because regions with high temperatures require high surface densities in order to supply sufficient viscous heating.

This scenario maintains thermal equilibrium provided that the gas opacity does not have a strong temperature dependence. A large opacity change affects the disk temperature because the opacity determines how freely the energy in the disk can escape into space. In zones of

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

partially ionized hydrogen (approximately 10 000 K) the H^- ion is an important opacity source. It is very temperature sensitive, with opacity increasing as T^{10}. In this case, if the midplane temperature is perturbed downward slightly, the opacity will drop dramatically, allowing more energy to escape into space. This causes the temperature to drop even further. Likewise, if the temperature is perturbed upward, the temperature will continue to rise. A region of the disk in this state will either heat or cool until it reaches the stable branches at the top or bottom of the s-curve. The lower branch of the curve is thermally stable because it is too cool for significant hydrogen ionization and the opacity due to molecular absorption has a weak temperature dependence. Likewise, the upper branch is thermally stable because hydrogen is mostly ionized, which also gives a weak temperature dependence for the opacity (Kramers opacity $\sim T^{-2.5}$).

The conditions at each radius in the disk correspond to some point on the $T-\Sigma$ curve, which is determined by the local accretion rate. If this dictates a temperature where hydrogen is partially ionized, the local solution will fall on the middle branch of the s-curve, which is thermally unstable. This region of the disk will either heat or cool to reach thermal equilibrium. If the temperature in this unstable region is perturbed downward the temperature will decrease until the lower branch is reached. However, the accretion rate into this region is too high for this portion of the $T-\Sigma$ curve. The surface density increases as matter enters the region at a rate greater than it is being transported inward. The temperature rises because of increased viscous heating and increased gas opacity. The local temperature and surface density both increase following the lower branch of the curve until the lower bend of the s-curve is reached. The region must then rapidly heat until the temperature equals that of the thermally stable upper branch of the s-curve. The local accretion rate is then too low for this hot state, and both the temperature and surface density decrease until the upper bend of the s-curve is reached. The region then cools until it reaches the lower branch of the s-curve. The entire process then repeats. For the entire disk to go into outburst a heating wave propagates to other regions of the disk. Fully time-dependent models show that this does happen.

Comparison with observations

The disk model makes predictions that can be tested observationally. Steady-state disk models predict a flux distribution of $F_\lambda \sim \lambda^{-7/3}$. The spectra of DNs in outburst show a match to this exponent to within ± 0.3. If the disk instability begins near the outside the disk radius should increase during outburst. Studies of the eclipse light curves of U Gem in outburst have shown this to be true. The disk diameter peaks at about 0.4 times the stellar separations just after the start of an outburst and declines to about 0.28 just prior to the next outburst. Also, in this type of an eruption, the far-ultraviolet region of the spectrum should brighten after the optical region. This is expected because the ultraviolet light comes from the hotter inner disk and the heating wave requires time to travel to the inner disk. As mentioned above, type A outbursts show this behavior. The theory also predicts that, when the rate of mass transfer is above a certain critical level, the accretion disk should in a stable, high state where the gas is totally ionized throughout. This means that high-mass-transfer-rate cataclysmic systems should not have outbursts. The novalike systems (which show no outbursts) have mass transfer rates above this limit while the DNs have accretion rates below this limit in good agreement with the theory (see also CATACLYSMIC BINARIES: CLASSICAL AND RECURRENT NOVAE). This appears to be a strongest confirmation of the disk instability theory.

Details of the onset of an outburst and the manner in which it spreads through the disk still need to be worked out. For example, several observers have found evidence that changes in the disk begin 1–2 days before the start of an outburst. These include changes in emission line strengths and widths and slight rises ($\sim$0.1 mag) in the continuum level. For the most part, current theory does not address these observations which contain valuable clues to the outburst trigger mechanism.

Uhuru (SAS-1/Explorer 42)

NASA satellite, launched from the San Marco platform off the Kenyan coast in 1970. The first satellite dedicated to x-ray astronomy. Completed an all-sky x-ray survey and studied individual sources. Discovered x-ray binaries, including Hercules X-1 and Centaurus X-1, and confirmed the variability of Cygnus X-1. Uhuru means 'freedom' in Swahili. (See also SMALL ASTRONOMY SATELLITE, EXPLORER.)

Ultraviolet Astronomy

Ultraviolet (UV) astronomy is the study of the electromagnetic radiation emitted by celestial bodies in the UV wavelength range, a portion of the spectrum simultaneously shielded by our own atmosphere and beyond the sensory limits of our sight.

Actually, the electromagnetic 'window' accessible to ground-based observers is quite limited, being virtually confined to the wavelengths the human eye is responsive to. In particular, the shielding effect of the Earth's atmosphere on the radiation coming from space becomes very high at wavelengths shortward of 320 nm, the adopted limit of the UV region of the spectrum. This phenomenon, mainly due to the absorption of oxygen and ozone, affects the entire UV and x-ray spectral regions, thus preventing astronomers from recording not only high-energy phenomena giving origin to x- or γ-rays, but also common processes (such as the thermal emission from hot stars) involving intermediate energies and producing mainly UV radiation. This obstacle could be overcome only when—starting in the 1960s—it became possible, by means of rockets and orbiting vehicles, to carry astronomical telescopes above the bulk of the atmosphere.

The nomenclature commonly adopted to split the UV domain is to some extent ambiguous. The wide term 'UV' often refers to the wavelength interval starting from the atmospheric cut-off (≈320 nm) down to the 'Lyman break', i.e. the limit of the hydrogen Lyman line series at ≈90 nm. The shorter-wavelength segment from the Lyman limit down to the beginning of the x-ray portion of the spectrum, arbitrarily taken at $\lambda \approx 6$ nm (or ≈200 eV, in x-ray nomenclature), is generally referred to as the 'extreme UV' (EUV). At the same time, the radiation whose wavelength is shorter than 200 nm (strongly absorbed by most gases) is frequently called, as a whole, the 'vacuum UV'. In the following I will keep to the convention of referring by 'far-UV' (FUV) to the region below Ly α (121.6 nm), by UV to the range between 121.6 and 200 mm, and by 'near-UV' (NUV) to the radiation emitted longward of 200 nm.

The advantage of accessing the UV range was manifold. First, as already pointed out, the majority of radiation emitted by stars whose photospheric temperature exceeds 10 000 K falls in the UV region (figure 1). The reason is that stars' energy distribution crudely follows Wien's law for an ideal radiator:

$$\lambda_{max}\, T = \text{constant} \qquad (1)$$

(where λ_{max} is the wavelength of maximum emission and T the temperature), thus showing the emission peak at shorter wavelengths as the temperature increases. As a consequence, one has to access the UV to properly record the energy distribution of the hottest stars as a function of wavelength, as well as their total energy output.

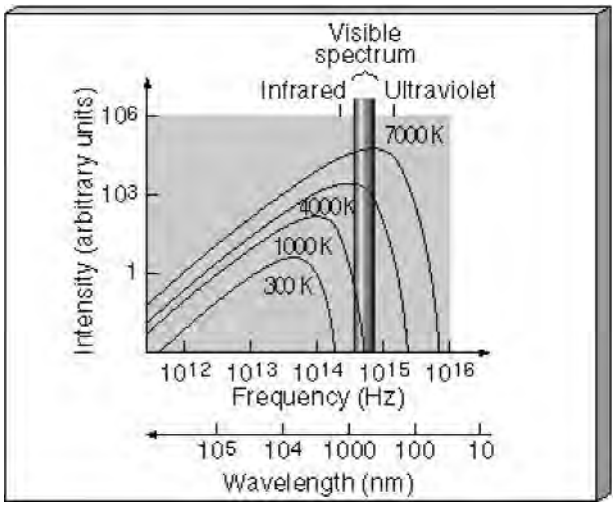

Figure 1. The energy distribution emitted by stellar photospheres as function of wavelength (or, equivalently of frequency) matches approximately the so-called Planck's curve, a mathematical idealization strictly correct for a body that absorbs all radiation falling upon it and thus—in a steady state—capable of re-emitting the same amount of energy. The curve shifts toward higher frequencies (shorter wavelengths) and greater intensities as the star's temperature increases. The net result is that stellar photospheres hotter than ≈10 000 K emit most of their light beyond the visible region of the spectrum. From Fortin E. 2002 *Above the Skies* (Harvard Extension School).

Secondarily, UV observations represent a superb research tool to investigate both physics and chemistry of astronomical bodies owing to the occurrence, in this wavelength range, of the so-called resonance spectral transitions, i.e. the most intense, ground-state transitions for most common atoms, ions and molecules.

Finally, when moving to UV, one can carry out deep surveys at significantly reduced levels of sky background. Actually, space observations ensure a sky 40× darker than at any wavelength from the ground at $\lambda \approx 200$ nm. This is obviously valuable when observing faint, extended sources such as distant galaxies.

One should not forget, however, that orbiting UV experiments are also influenced by specific background sources, namely the Earth's AIRGLOW and polar AURORA, as well as UV emission lines such as the far-UV hydrogen Ly α. Such a feature—ubiquitous within the solar system owing to the resonant scattering of solar photons off both interplanetary hydrogen and interstellar hydrogen flowing through interplanetary space—includes a particularly strong 'geocoronal' component, i.e. the Ly α resonant scattering produced off hydrogen atoms in the halo surrounding the Earth. As a consequence, unlike other sources such as the neutral oxygen O I 130.2 nm and 135.6

nm emission lines which affect only observations at low orbital altitudes, the geocoronal Ly α heavily interferes with UV observations obtained also by intermediate- and high-orbit (geosyncronous) satellites.

The Detection of UV Radiation

Although UV radiation is neither transmitted nor reflected as efficiently as are visible light and infrared (IR) wavelengths by optical components, the telescope construction techniques adopted to record the UV portion of the spectrum are still basically the same as those used in ground-based optical astronomy, consisting of parabolic–hyperbolic mirror combinations. One exception to this rule is the EUV waveband, as the observational techniques used in this wavelength range are more similar to those of x-ray astronomy. More precisely, observations in this range cannot make use of normal-incidence optics and the geometry of EUV telescopes has to ensure reflection via grazing incidence.

In order to provide a satisfactory reflection of UV radiation down to $\lambda \approx 100$ nm, surfaces are usually made of aluminum overcoated by MgF_2 (or LiF). High-efficiency normal-incidence reflection at shorter wavelengths, fulfilling the need to access the region shortward of the Lyman limit, can instead be reached by SiC mirror coatings.

As far as detectors are concerned, the present wide availability of silicon CHARGE-COUPLED DEVICES (CCDs), capable of recording photons over a very wide wavelength range (from 0.1 to 1000 nm), is appealing also in view of possible applications in the UV field. Such detectors are indeed the standard choice in many areas of today's astronomy and, together with MICROCHANNEL PLATE DETECTORS (MCP detectors) (see below), are currently replacing obsolete photographic emulsions to record UV observations (among recent missions, only the Shuttle-based Ultraviolet Imaging Telescope (UIT) still hosted image intensifiers/converters coupled to photographic films). When used as UV detectors, CCDs suffer from some limitations, however. Frontside-illuminated CCDs are insensitive to wavelengths shorter than 400 nm, for instance, although better performance in the UV can be obtained by resorting to thinned, back-illuminated chips. Moreover, a widespread practice intended to reach a suitable level of quantum efficiency (QE, i.e. the fraction of detected photons out of those reaching the detector) is to apply a fluorescing phosphor coating layer a few hundred nanometers thick, able to 'down convert' UV light, i.e. to absorb wavelengths shorter than 420 nm and re-emitting their energy in the visible region (around 520 nm). The CCD capable of the highest UV imaging sensitivity (down to $\lambda \approx 200$ nm) currently operating in space is the single 1024 pixel × 1024 pixel, back-illuminated detector of the Advanced Camera for Surveys—High Resolution Channel (ACS/HRC) on board the HUBBLE SPACE TELESCOPE (HST).

A step forward in UV light detection is now ensured by recently available MCP detectors. MCPs consist of a thin disk of a lead oxide glass crossed by many microscopic channels which act as individual photomultipliers and make the detector as a whole an image intensifier, when an electric potential is applied to its faces. They represent excellent two-dimensional (2D) detectors for the UV and EUV, when coupled with position-sensitive anodes which act as read-outs. Photon-counting, MCP-based detectors cope efficiently with many drawbacks of currently available CCDs, such as finite read-out noise, limited UV response and slow data access. This is the case of the state-of-the-art multi-anode microchannel array (MAMA) detectors which make both the Space Telescope Imaging Spectrograph (STIS) and the so-called Solar Blind Channel (SBC) of the just-mentioned ACS the most advanced UV-sensitive instruments currently operating on board HST. In the case of STIS, the combination of two MAMAs, whose sensitive wavebands slightly overlap (115–170 nm and 165–310 nm), ensures solar-blind, photon-counting capability (together with high spatial resolution imaging) over wide UV spectral range. A further step beyond CCD and MCP devices currently in use is expected shortly from the employment of a new class of detectors based on superconducting tunnel junction (STJ) technology. The main advantage of STJ detectors will be their ability to not only register each photon event but also to measure the wavelength of the detected photons over a very large spectral range, from FUV to the near-IR. What is more, STJ detectors hold particular promise in space-based UV astronomy, where their intrinsic spectral resolution is the highest and their QE exceeds that of the current instrumentation.

The Dawn of UV Astronomy

The technological development inherited from the World War II, especially in the field of long-range ballistic weapons, made it possible to take rocket-borne payloads above the atmosphere starting in the late 1940s. In particular, the first, unguided experiments flown by the Naval Research Laboratory (NRL) on board captured German V2 rockets returned unique information on the intensity and spectral distribution of the UV emission of the Sun. Space solar astronomy is indeed less demanding in terms of instrumentation sensitivity and rocket attitude control systems, thus forcing early UV astronomy to start as solar astronomy.

The rate of progress of UV space astronomy was quite fast, however. Actually, very simple, single-band UV photometers, flying on board unstabilized US Aerobee rockets were already able to provide the first UV observations of non-solar objects in the 1950s. More

Dirac House, Temple Back, Bristol, BS21 6BE, UK

exactly, the first UV data collected in space were broadband ($\Delta\lambda$=35 nm) flux measurements at 270 nm of 49 stars. UV spectrophotometric data were obtained for the first time a few years later (1961), by means of a scanning objective grating spectrometer flying again on board an Aerobee rocket, while the acquisition of spectra of pointed individual stars had to be postponed until 1965, when three-axis stabilization systems could be implemented on rockets. Although hampered by the very limited observing time available (a few minutes per flight), these pioneering observations (recorded on films to be collected after parachute landing) led to a revision of the temperature scale for hot stars and allowed astronomers to begin the study of mass loss phenomena from supergiant stars as well as to identify the UV interstellar absorption lines.

UV Imaging and Surveys

Although UV-sensitive facilities have brought unprecedented insights into many, largely unexplored, physical processes, their observations have been predominantly confined to the study of individual objects (as in the case of the International Ultraviolet Explorer (IUE) and HST satellites) or relatively small fractions of the sky (as in the case of recent balloon- or shuttle-borne imagers). As a consequence, our knowledge of the UV sky as a whole relies essentially on the pioneering survey mission of the TD-1 satellite in the early 1970s, whereas a sensitive, high-resolution (3–5 arcsec) all-sky UV survey is expected only with the launch of the Galaxy Evolution Explorer (GALEX) satellite (currently planned for April 2003).

In order to properly compare the capabilities of UV space imagers, one should be familiar with the most common units used in UV astronomy. Typically the fluxes of UV sources are given in 'monochromatic magnitudes' m_λ defined as follows:

$$m_\lambda = -2.5 \log (f_\lambda) - 21.175 \qquad (2)$$

where f_λ is the source flux density in erg cm^{-2} s^{-1} Å^{-1} at wavelength λ. As an alternative one can adopt the so called 'AB magnitudes' defined as

$$\mathrm{AB} = 2.5 \log (f_\lambda) - 48.60 \qquad (3)$$

where flux units f_ν are now expressed in erg cm^{-2} s^{-1} Hz^{-1}. The latter system has been specially defined to coincide with *V* magnitudes for a source with a flat spectrum. Its (wavelength-dependent) conversion into monochromatic magnitudes becomes m_{UV} = AB–2.26 in the middle of the UV domain (200 nm). An additional unit, used mainly to measure the UV background, is the count unit (CU), where 1 CU = 1 photon cm^{-2} sr^{-1} s^{-1} Å^{-1}.

With reference to the above photometric scales, the TD-1 catalog contains ≈58 000 sources brighter than m_{UV}=8.5, measured in four UV spectral bands centered at ≈ 155, 195, 235 and 275 nm. For comparison, the All-Sky Imaging Survey catalog to be provided by GALEX will contain ≈10^7 spiral/irregular galaxies and ≈10^6 quasi-stellar objects (QSOs), as well as ≈4×10^5 hot stars down to mag AB≈22 in two contiguous UV bands (135–180 and 180–300 nm).

TD-1's successful flight showed the potential of long-lived, UV orbiting observatories, i.e. of UV-devoted telescopes operating on board satellites. On the other hand, the advent of UV orbiters did not stop the development of other kinds of UV-oriented missions—both imagers and spectrometers—intended to exploit short-duration flights of rockets, stratospheric balloons and finally space shuttles. The first balloon-borne UV telescopes flown in the 1970s had the advantage of remarkably extending the observing time in comparison with sounding rockets, and although the observing window of these payloads floating at an altitude of ≈40 km is confined to the NUV owing to atmospheric extinction, long-duration balloon flights are still felt to be appealing enough to conduct all-sky surveys. Just as an example, upgraded versions of the French–Swiss balloon-borne FOCA experiment, which surveyed ≈70 sky square degrees imaging hundreds of galaxies down to a limiting magnitude m_{UV}≈19, will presumably fly in the future. Analogously, modern rocket-borne instruments such as the Narrowband Ultraviolet Imaging Experiment for Wide-Field Surveys (NUVIEWS) launched in 1996 turned out to be competitive in mapping the mid-UV background at a resolution of a few arcminutes. What is more, short-duration missions can be highly productive when multitask payloads are brought into space. This is the case for the two consecutive ASTRO-1 and ASTRO-2 Shuttle missions which hosted three co-mounted UV instruments: a UV imager (the UIT), a spectrometer capable of measuring UV fluxes down to the Lyman limit (the Hopkins Ultraviolet Telescope HUT) and the Wisconsin Ultraviolet Photo-Polarimeter Experiment.

Turning back to the orbiting telescopes which pioneered access to the UV sky, one should mention the rich dataset (consisting of pre-selected targets) of another successful mission, the Astronomical Netherlands Satellite launched into a polar elliptical orbit in 1974 and operated until early 1976. Its 22 cm diameter telescope focused UV light through a 2'.5×2'.5 aperture onto the focal plane of a spectrometer, thus sampling five, close UV spectral bands 15–20 nm wide starting from ≈150 nm.

A few additional experiments compensated for the lack of all-sky surveys by means of their high sky coverage. Among them one should mention the Far-Ultraviolet Experiment S201 which operated from the surface of the Moon during the Apollo 16 mission in 1972 assuring UV imagery of 10°–20° diameter fields, down to a limiting monochromatic magnitude m_{UV}≈12.

Two additional wide-field UV imaging facilities, namely the Wide-Field UV Camera (WF-UVCAM) and a first version of the Far-UV Space Telescope (FAUST), operated during the Spacelab 1 flight aboard Space Shuttle in the early 1980s. The WF-UVCAM's survey covered a large fraction of the sky, mostly in the southern hemisphere, taking advantage of its ultrawide field of view (66°), imaged with a resolution of 5'. FAUST was conversely designed to image a smaller field of view (≈8°) with a better angular resolution (1–2 arcmin). Unfortunately the high background experienced in orbit affected both experiments, whose data were recorded on photographic emulsions, and the best WF-UVCAM images did not record objects fainter than m_{UV}=9.3, while almost no objects were detected by FAUST. A second opportunity for this telescope came at the time an improved version flew on board the Space Shuttle Atlantis in 1992. This time the telescope, taking advantage of a modern MCP imaging detector, was capable of reaching a limiting magnitude m_{UV}=13.5 at 165 nm, as planned. Altogether FAUST's UV images covered a sky area of 0.33 sr (i.e. about 3% of the whole sky), thus ensuring UV photometry of more than 4000 star-like and extended sources.

Among UV archive images widely used are the data obtained by UIT. This instrument, namely a 38 cm telescope equipped with two selectable cameras providing both FUV and NUV 3 arcsec resolution images, gave extremely useful overall pictures of a wide variety of UV extended sources such as supernova remnants, globular clusters, OB associations, spiral galaxies and circumnuclear starbursts. These UV images of nearby galaxies are still highly valuable to date, owing to their relevance (as morphological templates) to high-redshift galaxies whose ground-based observations are preferentially made in the rest-frame UV (figure 2).

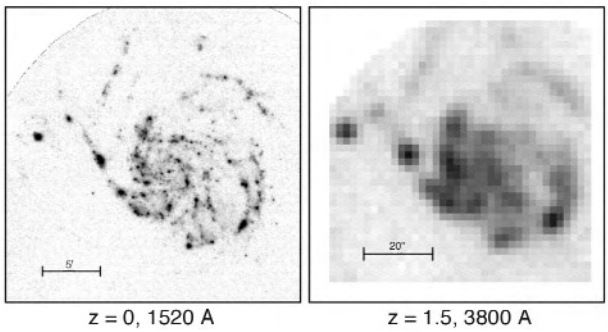

Figure 2. Left panel: a UV (150 nm) image of the luminous Sc galaxy M101 obtained by UIT. Right panel: a simulation of a galaxy with the same structure but 10× higher surface brightness at a redshift z=1.5 as observed by a 10 m class telescope. Owing to both reduced spatial resolution and changes in the galaxy's appearance with wavelength, the simulation is not easily recognizable as a normal spiral galaxy as seen at optical wavelengths. As a consequence, the observer could be induced to misinterpret such a difference as a genuine evolutionary effect. From Marcum *et al* 2001 *Astrophysics Journal Supplement Series* **132** 129.

UV Spectroscopy

As in any other field of observational astronomy, the amount of physical information carried by UV spectroscopy is much larger than that of simple imaging and/or photometry. This can explain the large effort devoted to taking into space UV spectrometers as early as possible in the history of space exploration, as well as the great scientific achievements of relatively simple facilities, like the IUE satellite.

UV spectrographs flown in the last few decades are characterized by improving performance in terms of limiting flux, sensitive spectral range and resolving power $R=\lambda/\Delta\lambda$ (a resolving power R=1000 corresponds to the ability to recognize individual features as close as a thousandth of their wavelength λ).

Among early successful instruments one has to include a satellite of the OAO series, i.e. the OAO-3, called COPERNICUS which was launched in 1972 and operated for eight years. Copernicus carried as the main UV experiment the UV Princeton equipment consisting of an 80 cm telescope and a grating spectrometer equipped with four UV-sensitive phototubes covering a short (95–145 nm) and a long (165–300 nm) wavelength range. The first high-resolution UV spectra (down to $\Delta\lambda$=0.5 nm) of early-type bright stars are due to this facility, although the primary goal of this mission was to make use of interstellar absorption lines, as seen against spectra of UV-bright stars, to estimate abundances in the interstellar medium (ISM).

The end of the same decade represented a turning point owing to the launch of the IUE. This long-lived, extremely successful satellite was brought into a geosynchronous elliptical orbit and operated as a guest observer facility from two stations located on either side of the Atlantic Ocean. Its instrumentation consisted of a 45 cm telescope with a 16' field of view, equipped with two echelle spectrographs covering two overlapping ranges from 115 nm to 335 nm. The majority of spectra were obtained through a large, oval aperture 10"×20" in size. The satellite could operate at low (R≈300) and high (R≈10 000) resolution, providing a spatial resolution orthogonal to the dispersion of ≈4". Its archive, containing about 108 500 spectra, is a unique heritage that the UV community will continue to exploit in the future.

A step forward in UV spectroscopy came with the two consecutive missions of the HUT telescope (see above) thanks to its unique ability to explore the UV energy distribution down to the Lyman limit (91.2 nm) and thus derive reliable temperature estimates for hot thermal sources (e.g. stellar populations including objects with T_e≈20 000–30 000 K). More precisely, HUT consists of a 90 cm telescope with a spectrograph covering the

Dirac House, Temple Back, Bristol, BS21 6BE, UK

82.5–185 nm region coupled with a photon-counting microchannel-plate intensifier providing a resolution of $\Delta\lambda$=0.3 nm.

UV-sensitive spectrographs have also operated on board HST since the beginning of its operational life. First-generation instruments were FOS and GHRS, both sensitive to UV wavelengths and largely complementary. The former UV–optical device operated at low and moderate resolution ($R\approx$250 and 1300) with a variety of apertures to optimize throughput, while two photon-counting detectors (digicons) could be used to select either a blue (115–550 nm) or a red (165–850 nm) channel. An interesting feature of FOS was its ability to isolate subarcsecond regions of an extended source. Conversely, GHRS was a UV-dedicated instrument capable of obtaining much higher-resolution spectra (up to $R\approx$ 80 000) of small wavelength intervals (from 28.5 nm to less than 1 nm). The above UV-sensitive spectrographs were replaced in 1997 by STIS, an innovative instrument making use of 2D detectors, thus providing spatially resolved long slit or slitless spectroscopy from 115 to 1100 nm from low to medium spectral resolution ($R\approx$600–14 000), together with high-resolution UV echelle spectroscopy up to a resolving power $R\approx$100 000.

The EUV

Overcoming the atmosphere's opacity by means of space-borne telescopes in not enough when moving to the EUV portion of the spectrum. Actually, at wavelengths shortward of the Lyman limit (91.2 nm) observations are hampered by the intervening opacity of the ISM, a phenomenon due to the line-of-sight atoms of hydrogen as well as of neutral and singly ionized helium (below 50.4 nm and 22.8 nm respectively). Moreover, as stressed above, a conventional optics consisting of curved reflecting mirrors would indeed absorb photons at wavelength shortward of ≈50 nm and the goal of reflecting the majority of such radiation can be achieved only by imposing sufficiently low incidence angles on traveling EUV photons. In other words, one has to resort to specifically designed telescopes, including a series of (metal) grazing-incidence surfaces, to focus EUV light.

Since the beginning of EUV astronomy interplanetary probes and manned spacecraft played quite a large role in this field. This is the case, for instance, for the earliest measurements of the EUV background (i.e. below Ly α) obtained by means of simple Geiger counters on board Soviet probes Venera 5 and 6. A later major step in the exploration of the EUV sky was made possible in 1975 during the the joint Apollo–Soyuz mission. Its EUV experiment—a 37 cm grazing-incidence telescope with selectable fields of view of a few degrees—discovered the first four EUV point sources, thus showing that, contrary to the prevailing opinion at that time, EUV astronomy was indeed possible. Other long-lasting experiments, namely modern UV spectrometers employing MCP intensifiers and covering the range 50–170 nm, were part of the scientific payload of Voyager 1 and Voyager 2 which started their journey into interplanetary space in 1977. A modified spare UV spectrometer (the EUVS experiment) built for the above Voyager program has been finally adapted to the currently operating Galileo spaceprobe, thus ensuring EUV/UV spectral capabilities from 54 to 128 nm.

The modern age of EUV astronomy came at the beginning of our decade thanks to the all-sky survey performed by the EUV Wide Field Camera on board the x-ray ROSAT satellite. Such a camera explored the whole sky in two, slightly overlapping, bands (6–14 nm and 11–20 nm) and the resulting final catalog contains 479 EUV sources, consisting mainly of hot white dwarfs and late-type (i.e. not hotter than the Sun) active stars.

An additional successful facility which, although brought into orbit in the Shuttle's payload bay, operated twice (in 1993 and 1996) as a free-flyer space UV/EUV telescope, was the German–US ORFEUS-SPAS platform. The ORFEUS (Orbiting and Retrievable Far- and Extreme Ultraviolet Spectrometer) instrument consists of a 1 m telescope equipped with two spectrographs, one of which, devoted to EUV, covered the region between 40 and 120 nm with a fairly high resolving power (R=3000).

Actually, the present-day reference dataset for knowledge of the EUV sky is represented by the source catalogs, images and the spectral atlas of the EXTREME ULTRAVIOLET EXPLORER (EUVE) satellite, which operated from 1992 until 2001. This facility included three grazing-incidence, co-aligned telescopes and an EUV spectrometer–deep survey instrument. The first three scanning telescopes, which are perpendicular to the spacecraft spin axis and possess a 5° field of view, allowed a complete survey of the EUV sky to be made in four bandpasses from 7 to 76 nm, while the fourth telescope could simultaneously scan the sky over a 2°×180° area along the ecliptic (i.e. the plane of the Earth's orbit). The latter telescope, aligned parallel to the spacecraft spin axis pointing away from the Sun, was allowed to integrate on a given source for a time as long as ≈0.5 h during a single orbit (versus a typical 500 s exposure of the main survey), so as to provide much deeper images. Altogether, EUVE obtained a vast amount of data from a largely unexplored region of the electromagnetic spectrum, thus ultimately giving to the field of EUV astronomy its own scientific identity, separate from other previously exploited spectral windows.

Highlights of UV Astronomy

The Solar System and The Sun

The study of cometary physics and Jupiter's auroral activity represents highly valuable achievements of UV astronomy. As far as the Jovian auroral phenomena are

Copyright © Nature Publishing Group 2003

and Institute of Physics Publishing 2003
Dirac House, Temple Back, Bristol, BS21 6BE, UK

concerned, one should be aware that current knowledge of their time-scales comes mainly from a successful coordinated IUE–Galileo probe UV campaign. More than that, UV observations of comets are studded with discoveries: IUE spectra of the comet IRAS–Araki–Alcock led, for instance, to the discovery of an unexpected molecule (S_2) never observed before in any astrophysical object, while more recent EUVE spectra of comet Hyakutake at 8–70 nm revealed for the first time the emission lines of ions that are brought to the comet by the solar wind and excited in charge exchange with cometary neutral species.

UV and EUV solar spectroscopy is presented in detail elsewhere in the *Encyclopedia* and the reader should refer to such a specific issue. It suffices to mention here the successfully operating solar experiments of the Solar and Heliospheric Observatory and Transition Region and Coronal Explorer, which have given unprecedented insight into the phenomena affecting the solar corona (such as the temperature structure and the 'seismology' of coronal loops), as well as into coronal plasma heating and the generation of the solar wind.

Stars

The impact of UV studies of stars is incalculably large, spanning an extremely wide variety of classes, evolutionary phases and phenomena. Roughly speaking, one can refer to three major subfields, namely studies of massive hot stars, (active) cool stars and binaries.

The role of very massive ((30–100) $M_{\odot}$) hot stars and their progeny (e.g. Wolf–Rayet stars and luminous blue variables) can be fully appreciated by taking into account that—when present—they dominate the appearance of their parent galaxies and, what is more, heavily affect their evolution through continuous mass loss, supernova explosions and ionizing radiation. Observations in the FUV domain are particularly well suited to characterizing the physics of strong stellar winds produced by the above stars (most of the strongest transitions of ionic species in their accelerated envelopes fall shortward of 200 nm) as well as to deriving the basic parameters of such extreme stars. This is the case, for instance, of a WO-type star (Sand 2) in the LARGE MAGELLANIC CLOUD (LMC), whose recent FUV spectrum obtained by the Far-Ultraviolet Spectrograph Explorer (FUSE) indicates a temperature $T_e \approx 150\,000$ K and a luminosity approximately 200 000× higher than that of the Sun. The evolution of such ultraluminous stars is so fast that this object is expected to undergo a supernova explosion within the next 10 000–50 000 yr. Surprising results have been obtained, again in the FUV, by observing the low-mass, very hot stars which expel huge, glowing layers of gas (the so-called planetary nebulae, excited by the UV radiation from the central star itself), while moving towards their final stage of white dwarf stars. In effect, when FUSE recently observed an object of this kind, namely the M27 nebula, it turned out that, although the central star is extremely hot, there is a lot of molecular hydrogen in the surrounding material, a discovery posing the unanswered question of how does molecular gas survive in such a harsh environment.

At the opposite end of the star temperature scale, UV data gave basic clues to the nature of activity in chromospheres and coronas of stars as cool as $T_e \approx 3000$ K. These objects, characterized in both the UV and the FUV spectral domains by a very weak continuum and a rich spectrum of emission lines formed in the regions going from the chromosphere to the corona (where the temperature grows from 4000 up to 150 000 K), show indeed spectra qualitatively resembling the chromospheric and transition region spectrum of the Sun, although with emission fluxes several orders of magnitude larger. The physical insight obtained by the study of UV emission lines of magnetically active stars is amplified by the occurrence of flares, i.e. energy release episodes in response to magnetic reconnection events. Their distribution in energy and relation to cool stars' activity and rotation has been fruitfully studied also in the EUV by means of the EUVE satellite.

Interacting binary systems such as symbiotic stars—consisting of a cool red giant and a hot, UV-bright white dwarf and thus characterized by highly energetic processes such as colliding star winds, nova-like outbursts etc.—are also quite suitable for UV investigations and have been extensively studied. Clues to the geometry of these binary systems also came from the study of the conversion of UV emission lines originating near the hot component into optical emission lines in the extended atmosphere of the cool giant (the so-called Raman scattering). Observers had instead to resort to EUV observations to succeed in detecting hot white dwarfs in Sirius-type, non-interacting binary systems containing a sufficiently hot (i.e. of the O, B and early A spectral type) main-sequence star. The reason is that the emission of the brighter star dominates here the radiation down to the UV and FUV regimes and neither IUE nor HST could be used to identify the degenerate companion.

Star Clusters

In globular clusters—old, roundish systems containing up to a million stars—the large majority of the population is quite cool. Their emission shortward of λ=200 nm comes indeed from a minority of stars crossing specific hot evolutionary phases. Among them have been identified single, highly evolved luminous stars which dominate the integrated UV light of the whole cluster, as well as populated 'tails' of lower-luminosity hot (up to $T_e \approx 20\,000$ K) core helium-burning stars which also emit most of their light in the UV domain. In addition, the present ability (by means of HST) to detect much fainter UV sources

Copyright © Nature Publishing Group 2003

and Institute of Physics Publishing 2003
Dirac House, Temple Back, Bristol, BS21 6BE, UK

is offering a more complex and potentially interesting scenario where other star classes (eruptive variables, the mysterious 'BLUE STRAGGLERS', etc.) also play a role.

HST UV imaging opened recently the possibility of studying also what might be the progenitors of today's globular clusters, namely a population of compact, young star clusters located in a variety of starburst environments (preferentially circumnuclear star-forming rings in galaxies). The most luminous of them—generally termed 'super star clusters' (SSCs)— could indeed survive as bound entities for more than 10 billion years, thus representing, on the basis of their radii, high luminosities, and presumably high masses, genuinely young globular clusters.

Supernova 1987A

The nearby supernova which appeared in the LMC in February 1987, monitored on a regular basis with all possible telescopes since the time of the explosion, is by far the best-studied object of its class. It is specifically mentioned here because a substantial contribution to the knowledge of its early evolution came from intensive UV spectroscopy ensured by the IUE satellite and, since the time of its launch in 1990, by HST. Among the exciting results obtained by means of UV observations one has to mention the identification of the supernova progenitor (which unexpectedly turned out to be a blue supergiant star), the possibility of deriving the complex structure of the intervening medium both in our own Galaxy and in the LMC toward the UV-bright supernova and an accurate determination of the distance to the supernova. Moreover, the fast evolution of the supernova remnant is still giving rise to phenomena on a time-scale of a few years (such as the appearance of brightening spots on the equatorial ring surrounding the exploded star, caused by radiative shocks created where the blast wave strikes dense gas regions). The physics of this phenomenon is currently under study by means of UV (STIS) spectra on board HST.

Galaxies

Observations of galaxies at UV wavelengths represent a highly effective means of investigating both their hot stellar content and energetic phenomena in their central regions. The latter is obviously the case of galaxies hosting active galactic nuclei (AGN). These two classes of UV sources reflect, in turn, two distinct mechanisms (thermal and non-thermal) of radiation emission.

Stellar Populations in Galaxies

For disk-dominated galaxies UV imagery offered a direct way of recognizing active sites of star formation at different scales (spiral arms, nuclear rings, star-forming complexes, etc.) as well as of estimating the rate at which new stars form. Moreover, the patterns of star-forming sites seen in the UV for nearby galaxies of different morphologies turned out to be of great relevance to reconstructing the morphological class of very distant galaxies whose visible and IR images recorded by ground-based telescopes do actually show—owing to cosmic expansion—their rest-frame UV emission (figure 2). The role of UV observations of young, massive stars became even more pronounced for galaxies hosting a 'starburst', i.e. a major event of star formation dominating their energetic output. For these objects, the ability to address many key issues, such as starburst morphology, the nature of the so-called SSCs and the impact of dust obscuration, is largely dependent on the availability of UV images.

The access to UV spectroscopy proved, in turn, to be imperative for characterizing stellar populations' temperature, metal content and age. In particular, the continuing decrease of UV emission of aging starbursts can be properly modeled by means of synthetic spectral energy distributions (SEDs) of single-generation stellar populations, thus providing a reliable dating method up to ≈1 Gyr. More than that, the sensitivity of the UV to stellar properties proved to extend even to the relatively cool, lower-mass main-sequence stars which dominate the mid-UV light after the exhaustion of star formation activity so that even the mid-UV region of the spectrum can be used for dating purposes for both local and distant galaxies (figure 3). Analogously, UV and FUV spectra of local starbursts provided by IUE, HUT and FUSE now ensure unique templates to quantify the chemistry and age of galaxies experiencing major star formation episodes in the early universe. Finally, UV turned out to be an effective window to understand also the late evolution of low-mass stars dominating spheroidal systems, such as elliptical galaxies and spiral bulges. These systems are indeed characterized by a sharp rise of their spectrum shortward of ≈200 nm (generally referred as

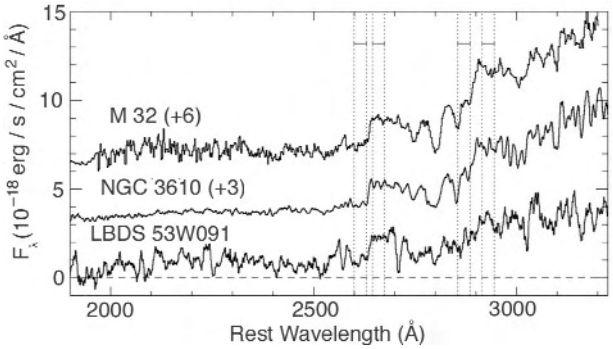

Figure 3. Comparison of the rest-frame UV spectrum of the galaxy LBDS 53W091 at z=1.5 and those of the local ellipticals M32 and NGC 3610. The vertical lines indicate the spectral intervals used to measure the breaks observed in the energy distribution. Such a comparison indicates that the age of the distant galaxy is not lower than ≈4 Gyr. From Spinrad *et al* 1997 *Astrophysical Journal* **484**, 581.

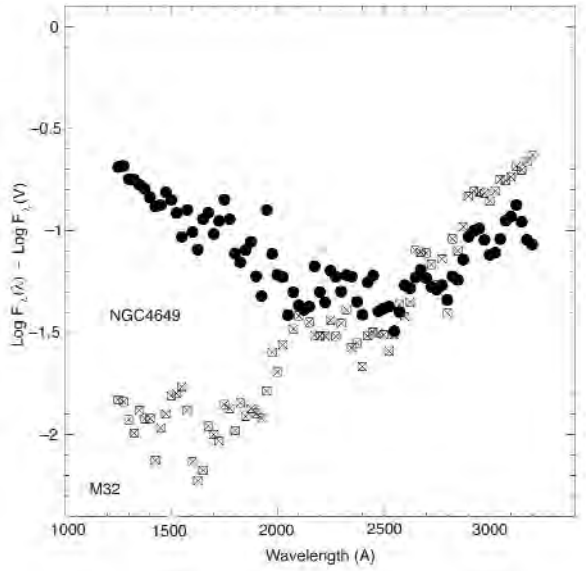

Figure 4. Comparison between the IUE energy distributions of NGC 4649, a typical metal-rich giant elliptical (full circles) and the low-luminosity metal-poor elliptical M32 (crossed squares), normalized to the visual flux. The adopted flux scale is logarithmic. Note the striking difference between the two spectra in the UV region dominated by the hottest stars, as opposed to the approximate match longward of ≈200 nm.

the 'UV-upturn' phenomenon), ascribed to some fraction of hot, evolved stars (figure 4). Since the onset of this phenomenon does depend on both the composition and age of the old populations, observers in the UV have at their disposal a second major probe of stellar populations (besides the strong UV emission of young, massive stars). More precisely, although the first hint of this feature came from the pioneering observations of the ANDROMEDA GALAXY bulge by means of the OAO-2 satellite, a much deeper insight into the origin of this behavior has been reached only by means of the large body of data recorded by IUE. IUE spectra showed indeed that the amplitude of this phenomenon depends on the chemical composition, as the higher the mean metallicity (percentage of elements heavier than hydrogen and helium) of the galaxy, the higher its UV flux. A further constraint on the nature of stars causing the UV upturn—namely its narrow range in temperature (T_e≈20 000–24 000 K)—came later from the spectra obtained by means of HUT. The maximum emission of hot stars of such a temperature falls indeed around 105 nm, just within that telescope's sensitive range.

Since then astronomers have faced the need to identify one (or more) evolved stellar components sufficiently hot, bright and long lived as to provide the observed UV flux and such a debate is still going on. While both observers and theoreticians favor the hottest, core-helium burning objects known as extreme horizontal branch stars and their progeny as the sought hot source, one cannot yet firmly establish whether they belong to a metal-poor or metal-rich minority of the population. This last issue, in turn, is quite important in the context of galaxy evolution, especially if the UV upturn onset is related to the attainment of a given maximum metallicity in the stellar population. If this is the case astronomers could indeed make use of it to constrain both metallicity and age of distant ellipticals.

Active Galactic Nuclei

Prolonged, IUE-based spectral monitoring campaigns aiming at understanding continuum and emission-line variability of Seyfert 1 galaxies (see SEYFERT GALAXIES) turned out to be quite successful, confirming the existence of time delays between continuum variations in different parts of the spectrum as well as of broad emission lines in response to UV continuum variations. Such phenomena, in turn, impose strict constraints on the theoretical models of these massive black hole candidates.

At the same time UV imaging showed its unique potential in the study of galaxy nuclei. Unlike optical and IR images of elliptical and bulge-dominated galaxies—dominated by the emission of surrounding cool stars—shorter-wavelength pictures permit nuclear non-thermal sources to show up over the galaxy stellar background. This, in turn, permits better study of known nuclei and searches for objects hosting low-luminosity activity. Such contrast enhancement made possible, for instance, the discovery of UV flares at the center of optically normal galaxies which would have been lost if recorded in other wavebands. AGN have also been successfully used as cosmic 'lighthouses' in the UV to investigate the properties of absorbing systems at high redshifts. In particular, the observation of high-z quasars enabled IUE (and subsequently to HUT, HST and FUSE) to explore the rest-frame EUV portion of their spectrum, thus leading to the detection of the continuous depression of the flux blueward of the He II Ly α emission line at 30.4 nm due to the singly ionized helium (He^+), the most abundant absorbing ion in low-density regions of the young universe. Such a phenomenon is known—by similarity to the effect expected for neutral hydrogen—as the He II Gunn–Peterson effect.

Interstellar (and Intergalactic) Medium

For a long time it has been well known that the space between stars is filled by highly rarefied gas and microscopic solid particles, generally referred to as 'interstellar dust'. UV spectroscopy provided the tool to properly investigate the composition and physical conditions of interstellar gas by analyzing the strongest absorption features of common elements (such as C IV, N V and O VI ions) and molecular species (such as H_2 and CO) towards bright stars. The UV continuum shape gave, in turn,

Copyright © Nature Publishing Group 2003
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2003
Dirac House, Temple Back, Bristol, BS21 6BE, UK

information on the constituents of dust particles, showing, for instance, that the extinction they operate on the UV light shows a typical 'bump' around 220 nm. Likewise, the vast regions between galaxies and groups of galaxies is permeated by a tenuous gas, made up primarily of hydrogen and helium atoms, called the intergalactic medium (IGM). The amount and composition of this widespread cosmic component can be studied by recording the absorption features it produces in the spectra of distant quasars. Very fruitful observations of these kinds obtained by FUSE allowed astronomers to identify helium absorptions in the FUV that have no corresponding hydrogen absorptions in optical, ground-based spectra along the same line of sight. Although the IGM is very tenuous, the amount of matter locked up in such a previously invisible component is huge, and its existence must be taken into account in current cosmological models.

UV Background

As noted above, the FUV background, i.e. the diffuse astronomical flux incident upon the Earth at wavelengths of 91.2–200 nm, is quite faint (mainly because of the zodiacal light's dramatic decrease below λ=250 nm) and, as such, does offer a window of very low sky contamination for observations of objects of low surface brightness. On the other hand, a proper, uncontaminated estimate of the true diffuse FUV background is hampered both by the terrestrial airglow and the galactic background, resulting from the scattering of the UV radiation field by interstellar dust. In spite of that, different UV-sensitive imagers (namely the rocket experiment NUVIEWS and the STIS instrument on board HST) have recently provided reliable measurements of both astronomical components. In particular, the galaxy contribution at λ 174 nm has been successfully mapped by NUVIEWS with a resolution of 5–10 arcmin over a substantial fraction of the sky, while the true diffuse FUV background along a line of sight with very low galactic neutral hydrogen column and without any significant contribution from airglow has been estimated by STIS (after masking Galactic and extragalactic sources to very faint magnitudes) in the bandpass 145–190 nm.

UV Telescopes Currently in Operation

The highly successful observations of FUSE, launched on 24 June 1999, are enhancing the role UV astronomy is playing at the beginning of the new century. FUSE consists of four co-aligned 39 cm × 35 cm mirror telescopes coupled with four spherical, holographically ruled gratings. It makes use of two MCP detectors and is specifically designed to obtain high-resolution spectra (R≈24 000–30 000) in the range between the Lyman limit and Ly α emission (90.5–118.7 nm).

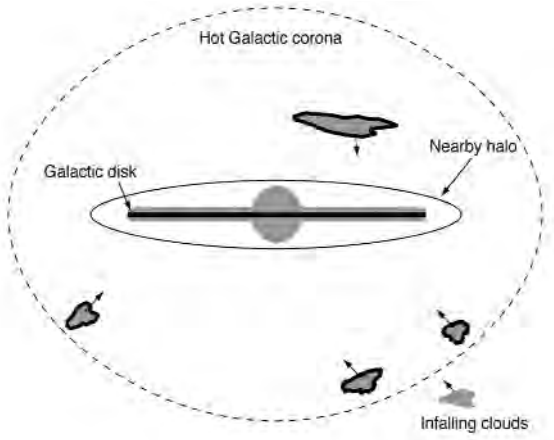

Figure 5. FUSE found evidence for a corona of tenuous hot gas much more extended than the well-known hot halo around the disk of the Milky Way. Clouds of gas raining into the Galaxy from the outside are heated as they pass through this corona—much like a meteor heats up as it passes through the Earth's atmosphere—and eventually become detectable in the FUV by FUSE. This hot, high-velocity gas has been detected at over 50 directions looking through our Galaxy's halo, indicating that it is widely distributed around our Galaxy.

The access to this largely unexplored FUV window represents indeed a breakthrough for many poorly known astrophysical fields. In effect, although previous missions did provide brief glimpses into the above wavelength range (suffice it to remember the Copernicus mission which opened the FUV window in the 1970s, and the two HUT and ORFEUS telescopes flown on Space Shuttle missions in the 1990s), FUSE is able to observe sources more than 10 000 times fainter than Copernicus at a resolution many times better than that obtainable with either HUT or ORFEUS. Thanks to this increase in sensitivity FUSE can explore, for instance, the outer reaches of the Milky Way (figure 5) as well as making use of quasars as continuum sources for absorption line studies of distant gas clouds (figure 5).

FUSE is a principal investigator (PI) class mission, and as such was developed to carry out several primary scientific objectives proposed by the PI science team and selected by NASA. The main programs include (i) a survey of O VI absorption in the Milky Way disk and halo and the Magellanic Clouds, in order to determine the physical properties and distribution of hot gas, as mentioned above, (ii) determining the abundance of deuterium in a wide range of Galactic environments, (iii) exploring the nature and distribution of the hot IGM and (iv) understanding the role of molecular hydrogen in circumstellar environments and planetary atmospheres.

Among other operating, UV-sensitive facilities, one has to mention again the ACS, a third-generation imager installed on board HST during Servicing Mission 3B in March 2002. This instrument actually consists of three

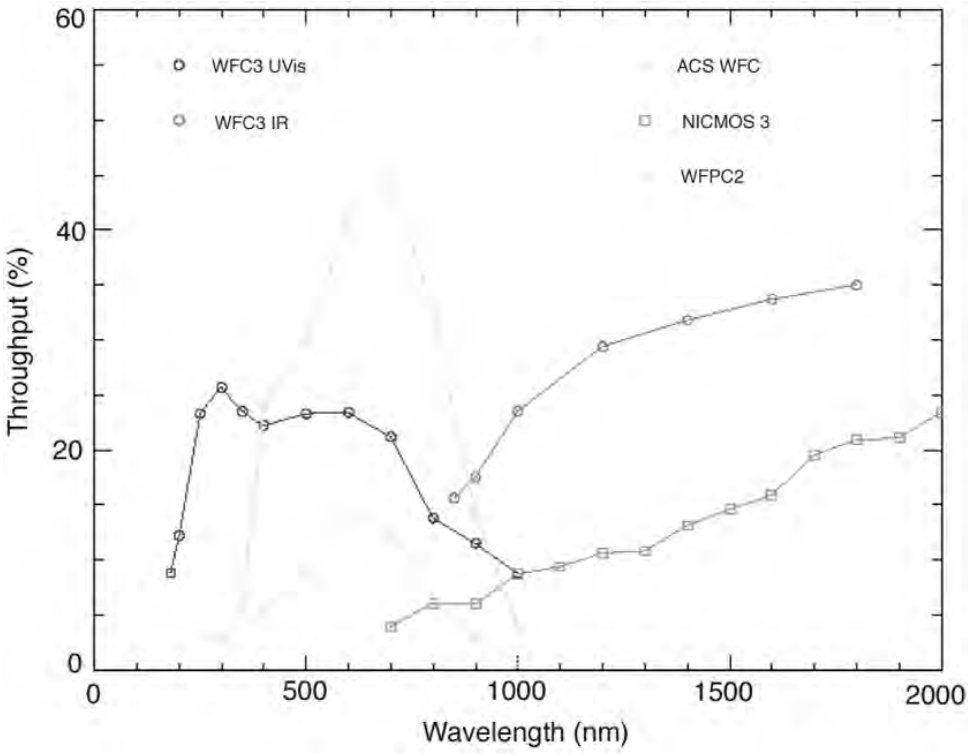

Figure 6. Expected throughput for the WFC3 instrument compared with those of other HST imagers. Note the extension into the UV of the wide-field imaging capabilities of HST ensured by the WFC3 instrument.

cameras covering a large spectral region from the UV to the near-IR (120–1000 nm). As already pointed out, its UV-devoted imagers are the SBC, equipped with a photon-counting MAMA detector (whose sensitivity is confined to the range 115–170 nm) and the HRC equipped with a CCD detector operating longward of λ=200 nm. Present-day UV astronomy is also taking advantage of a piggy-back UV instrument belonging to an x-ray-devoted mission, namely the UV/Optical Monitor on board the XMM-Newton satellite. This telescope, operating in the 170–650 nm range, can provide imaging on the central region of the 17 arcmin × 17 arcmin x-ray field of view.

Forthcoming UV Missions and the Future

As already mentioned above, among survey-devoted projects, a highly valuable scientific return will come from GALEX, expected to be launched in April 2003. GALEX is intended to obtain a series of spectroscopic and imaging surveys in the range 130–300 nm in order to study both the UV properties of local galaxies and the star formation and metal production history of galaxies over the redshift range $0<z<2$.[1]

At the same time, the highly improved HST UV imaging capabilities ensured by the recent deployment of ACS will be further expanded when the state-of-the-art Wide Field Camera 3 (WFC3) is put into operation on board HST during the last servicing mission (scheduled for early 2005, following Columbia's accident). This instrument is configured as a two-channel camera. The incoming beam, once corrected for spherical aberration in the HST primary mirror by means of a two-element optical system, is sent to either a near-IR channel or a UV–visible channel. The latter will image a 160 arcsec × 160 arcsec field, thus providing unprecedented wide-field imaging capabilities in the UV down to $\lambda\approx$200 nm (figure 6).

The last HST servicing mission will also include the replacement of the spherical aberration corrective optics—no longer necessary after the removal of the Faint Object Camera—with the Cosmic Origins Spectrograph (COS), a medium resolution spectrograph specifically designed to operate into the NUV and mid-UV. COS—optimized for observing faint point sources with intermediate spectral resolution ($R\approx$20 000)—consists of two channels: an FUV channel that is sensitive in

[1]Owing to the expansion of the universe the light coming from distant galaxies shows a redshift (expressed as $z=\Delta\lambda/\lambda$ in terms of increased wavelength), thus appearing graually shifted toward the red with increasing receding galaxy velocity which, in turn, reflects increasing distance and lookback time. As a consequence, a given redshift range Δz corresponds to a well-defined interval in lookback time, once a specific cosmological model is chosen.

the 115–177 nm wavelength range and an NUV channel that operates between 170 and 320 nm. Taking advantage of its design, which minimizes the number of reflections (thus ensuring a dramatic improvement in sensitivity to faint objects over previous UV spectroscopic instruments flown aboard HST), it will permit several major issues in current astrophysics to be addressed, such as the properties of QSO absorption line systems and the IGM, the dynamics of the ISM in galaxies and galaxy halos, as well as the UV extinction in the Milky Way and the study of volatile gases in the atmospheres of solar system bodies.

The second half of the current decade should finally see the deployment of the World Space Observatory (WSO/UV). This spacecraft—to be regarded as a UV-devoted astrophysical observatory rather than a targeted mission—will consist of a 1.7 m diameter telescope equipped with both spectroscopic and UV-imaging instrumentation. More precisely, it will include a composite spectrograph capable of both high ($R \approx 60\,000$) and low ($R \approx 1000$) resolution, as well as two UV imagers—one for maximum spatial resolution, one for maximum sensitivity—operating essentially in the same wavelength range (110–340 nm).

WSO/UV will be innovative in many respects. For instance, it will be brought into an L2 orbit, i.e. it will operate from a point in space known as the second Lagrangian point located about 1.5 million km from the Earth in the anti-Sun direction. Such an orbit, besides being a very stable thermal and radiation environment, does offer the possibility of long uninterrupted observations, since Earth, Moon and Sun are permanently behind the spacecraft viewing direction. In addition, the approach chosen for the planning and execution of the WSO/UV will ensure significant cost savings, while facilitating the participation in space science of new countries.

Bibliography

A summary of all fields of UV research is given in the conference volume *Ultraviolet Astrophysics Beyond the IUE Final Archive*, eds W Wamsteker and R González Riestra, ESA SP-413 (1998).

A concise history of UV space programs is compiled by De Martino D and Buson L M 1999 UV space missions: from the past to the future *Memorie della Societa Astronomica Italiana* **70** (2) 315, while the specific issue of space surveys is discussed by Brosch N 1999 Ultraviolet sky surveys *Experimental Astronomy* **9** 119.

A description of the FUSE telescope, its performance and scientific background is given by Moos H W, *et al* 2000 *Astrophysical Journal* **538** L1; an analogous description for the GALEX satellite can be found in Bianchi L, *et al* 1999 *Memorie della Societa Astronomica Italiana* **70** (2) 365; readers interested to the WSO project should instead retrieve from the website http://arXiv.org the preprint astro-ph 0209333 by M A Barstow *et al*.

The most promising UV detectors under development are presented in *Ultraviolet–Optical Space Astronomy Beyond HST* (*ASP Conf. Series 164*) (1999) by O H W Siegmund (MP detectors) and P Jakobsen (STJ detectors).

Ulugh Beg (1394–1449)

Astronomer, born in Soltaniyeh, Timurid, Persia (now Iran), the grandson of the Asian conqueror Tamerlane, and under his father's patronage built a large observatory in the city of Samarkand, directed by Ali-Kudschi, with Al'Kashi and Kadizada amongst the staff. The observatory was well equipped with large instruments that revealed errors in Ptolemy's data. Ulugh Beg and the staff observed the positions of the Sun, the Moon, the planets and 992 stars, publishing a catalog *Zij-i Sultani*. The book of tables contained trigonometric functions. Ulugh Beg also wrote poetry and history. When his father died, he reigned briefly as ruler of the Timurid empire but was overthrown and slain at Samarkand at the instigation of his own son, Abd al-Latif.

Umbriel

A mid-sized satellite of Uranus, discovered by William Lassell in 1851. Its diameter is 1170 km and it orbits the planet at a distance of 266 000 km. The satellite was not well imaged by Voyager 2; an ancient, cratered surface was visible, broken only by the bright-floored crater Wunda (diameter 160 km). Umbriel appears to be a primitive, undifferentiated body: one that has never melted internally and segregated into a core and mantle, and has remained largely geologically inactive.

See also: Uranus.

Uncertainty Principle

A principle, named after the German physicist Werner Heisenberg (1901–76), which states that it is impossible to know simultaneously the precise position and momentum of a subatomic particle.

In order to measure the position of an electron, for example, it has to be observed. In order to observe it, we have to shine light on it. Because photons (particles of light) carry energy and momentum, each time a photon strikes an electron, the electron is deflected in an unpredictable way, so inducing an element of uncertainty into its velocity and momentum. The position of an electron cannot be measured to an accuracy much better than the wavelength of the illuminating radiation. The shorter the wavelength, the better the positional accuracy but the higher the energy and momentum of the illuminating photons and the greater the resulting uncertainty in momentum. As Werner Heisenberg proposed in 1927, the uncertainties in position (Δx) and momentum (Δp) are related as follows: $\Delta x \Delta p \geq h/4\pi$, where h is the Planck constant. Similar uncertainties exist in other pairs of measured quantities, such as energy and time. If the energy of a microscopic system is measured over a time interval Δt, the uncertainty in the measured energy (ΔE) is related to Δt by the following relation: $\Delta E \Delta t \geq h/4\pi$. The shorter the time interval, the greater the uncertainty in energy.

When the equivalence between mass, m, and energy, E, is taken into account ($E = mc^2$, where c denotes the speed of light), the uncertainty relationship between energy and time has important consequences. For example, over a very short interval of time, there is inherent uncertainty about the quantity of energy (ΔE) contained in any microscopic volume of space. If the time interval (Δt) is sufficiently short, the uncertainty principle implies that the volume may contain sufficient energy to create particles of mass $m \leq \Delta E/c^2$, provided that those particles vanish again before the end of the time interval (in practice, particle–antiparticle pairs form and mutually annihilate within time interval Δt). Such particles, which are called virtual particles because they cannot directly be detected, play an important role as force-carrying particles in quantum theories of the fundamental forces. The higher the mass of the virtual particle, the shorter its permitted lifetime. Because no particle can travel faster than the speed of light, the range to which a virtual particle can convey an influence is itself inversely proportional to its mass; thus forces that are conveyed by high-mass particles act over short ranges, while those that are conveyed by low or zero-mass particles have long, or infinite, ranges.

United Kingdom Infrared Telescope

The 3.8 m United Kingdom Infrared Telescope (UKIRT) is the largest telescope in the world dedicated solely to observations at infrared wavelengths. UKIRT is sited near the summit of Mauna Kea, Hawaii, at an altitude of 4194 m. UKIRT was designed and built in the UK in the 1970s on a low budget. A recent program of upgrades has resulted in outstanding image quality, approaching the diffraction limit in the K band in the best seeing conditions.

The current main instruments in the near-infrared, both with polarimetry capability, are the CGS4 spectrometer (providing resolutions from 400 to 40 000), and the UFTI imager. These will be largely superseded in 2001 by UIST, a near-infrared imager/spectrometer. A mid-infrared imager/spectrometer Michelle (covering 8 to 25 micron) is due to be delivered in 2000. From 2003 a large fraction of UKIRT time is expected to be devoted to deep surveys using a new wide-field camera (WFCAM), and covering several thousand square degrees in J, H, K—the infrared equivalent of the SLOAN DIGITAL SKY SURVEY.

The telescope is owned and funded by the United Kingdom PARTICLE PHYSICS AND ASTRONOMY RESEARCH COUNCIL and operated along with the JAMES CLERK MAXWELL TELESCOPE by the staff of the Joint Astronomy Centre, located in Hilo.

Universal Distance Scale

The HUBBLE CONSTANT is the local expansion rate of the universe, local in space and local in time. The equation of uniform expansion is

$$v = H_0 r \tag{1}$$

where v is recession velocity and r is distance from the observer. To measure the proportionality constant, we adopt a definition of the Hubble constant as the asymptotic value of the ratio of recession velocity to distance, in the limit that the effect of random velocities of galaxies is negligible. In galactic structure the velocity of the local standard of rest has wider significance for the dynamics of the Milky Way than the velocity of the Sun. We have to abstract the Hubble constant from local motions in a similar way.

Existence proofs of the Hubble constant so defined, that we would still accept today, include the Hubble diagrams for cluster ellipticals (Sandage and Hardy 1973), for the Arecibo clusters (Aaronson and Mould 1986)[1] and for type Ia supernovae (Hamuy *et al* 1996).

It is also desirable to employ the Hubble constant in models which apply to larger spatial and temporal scales. The present value of the Friedmann model's $\dot{a}/a$, generally acknowledged as the standard model of the universe, is H_0. The expansion age of the universe is H_0^{-1} to a factor of order unity. If the standard model of cosmology were the Einstein–De Sitter model, then that factor would be two-thirds.

How to measure the Hubble constant

Three current schools of thought on this subject are represented in *Critical Dialogues in Cosmology* (Turok 1996). Two of these schools see the CEPHEID PERIOD–LUMINOSITY RELATION for Cepheid variable stars as crucial for establishing the distances of galaxies within 20 Mpc, which then calibrate 'standard candles'. These secondary distance indicators reach out into a region where an asymptotic ratio of recession velocity to distance can be sought.

Supernova Ia standard candles

The SUPERNOVA phenomenon results from instability in the equation of state of the degenerate material in the interior of WHITE DWARFS. According to Branch and Tammann (1992) SNeIa are explosions of a standard maximum power. Cepheid distances can be measured to some of the host galaxies.

The Hubble Space Telescope key project

The key project strategy has been fully described by Kennicutt *et al* (1995), and involves calibration of the infrared TULLY–FISHER RELATION and the equivalent dynamical relation for ELLIPTICAL GALAXIES, the (D_n σ) relation. Also calibratable from key project Cepheid distances are surface brightness fluctuations in galaxies, the globular cluster luminosity function, the planetary nebula luminosity function and the expanding photospheres method for type II supernovae.

One-step methods

Critics of both the above approaches point to the propagation of errors in a three-step ladder from trigonometric parallaxes to Cepheids to secondary distance indicators to H_0. One-step methods to determine H_0 include GRAVITATIONAL LENSING of distant QUASARS by intervening mass concentrations, which results in measurable phase delays between images of the time-varying input signal from the source. Where these phase delays can be accurately determined, and when the model mass distribution can be uniquely inferred, they directly lead to z/H_0, where z is the REDSHIFT of the lens (Turner 1997).

Compton interaction between the microwave background and hot gas in clusters of galaxies (the SUNYAEV–ZELDOVICH EFFECT) allows the physical size and distribution of the absorber/scatterer to be inferred, at least in projection, if the properties of the hot gas are also constrained by direct detection in x-rays. A distance can be determined by comparing the angular and physical projected size (Lasenby and Jones 1996).

The Large Magellanic Cloud (LMC)

The LMC is an anchor-point of the extragalactic distance scale. From the LMC it is possible to calibrate essentially all of the secondary distance indicators using the Cepheid PL relation.

The HIPPARCOS revision of the Cepheid PL relation, designated [H] in table 1, brings trigonometric PARALLAXES (Perryman *et al* 1997) to bear on the calibration in place of cluster main sequence fitting. Although this is a step forward in principle, the signal-to-noise of the parallax measurements, the short periods of the nearby Cepheids and the need for a fuller photometric study of the Hipparcos stars combine to render their impact on the problem uncertain at this stage.

The HST key project has adopted an LMC distance modulus of 18.50 ± 0.13 mag corresponding to 50 ± 3.2 kpc. The adopted reddening is $E(B-V) = 0.10$ mag.

Calibration of the Tully–Fisher relation

The Tully–Fisher relation is a luminosity–linewidth correlation for SPIRAL GALAXIES (Fisher and Tully 1977). Sakai *et al* (1999) present a calibration of $BVRIH_{-0.5}$ Tully–Fisher relations based on Cepheid distances to 21 galaxies within 25 Mpc, and they go on to determine the Hubble constant based on 23 clusters of galaxies within 10 000 km s^{-1}. Primarily, these are clusters studied by Giovanelli *et al* (1997). They obtain $H_0 = 71 \pm 8$ km s^{-1} Mpc^{-1}.

Like Giovanelli (1997), Sakai *et al* find that the effect of incompleteness biases in their sample is small (cf Sandage *et al* 1995, Teerikoorpi 1997) and correctable.

[1] But note that velocity perturbations as large as 5% may exist on these scales (Lauer and Postman 1994).

Table 1. The distance of the Large Magellanic Cloud.

Distance indicator	$m-M$	Reference
RR Lyrae	18.54 ± 0.07	Walker (1992, 1993a, b)
MACHO RR Lyrae	18.48 ± 0.19	Alcock *et al* (1997)
Cepheids	18.47 ± 0.15	Feast and Walker (1987)
Bump Cepheids	18.51 ± 0.05	Wood *et al* (1997)
Cepheids [H]	18.70 ± 0.10	Feast and Catchpole (1997)
Cepheids [H]	18.57 ± 0.11	Madore and Freedman (1998)
SN1987A	18.50 ± 0.13	Panagia *et al* (1991)
SN1987A [E]	$<18.44 \pm 0.05$	Gould and Uza (1998)
Red clump		Stanek *et al* (1998)
Eclipsing binaries	18.44 ± 0.07	Pritchard *et al* (1998)
Adopted	18.5 ± 0.13	

The (D_n σ) relation for ellipticals

The analogous scaling relation for elliptical galaxies relates velocity dispersion and isophotal diameter (Burstein *et al* 1987). Mould *et al* (1996) selected all the groups with four or more (D_n σ) measurements from Faber *et al* (1989) and renormalized their distances so that the geometric mean of that of the Fornax, Virgo and Leo groups was 15 ± 1 Mpc, which is obtained purely from Cepheid distances. Kelson *et al* (1999) used a similar approach to calibrate the fundamental plane of radius, surface brightness and velocity dispersion. They obtained $H_0 = 78 \pm 10$ km s^{-1} Mpc^{-1} from a sample of clusters with a mean redshift of approximately 6000 km s^{-1}.

Supernovae

There has been significant progress in the discovery, analysis and understanding of supernovae in recent years, not least in the area of theoretical models (Hoflich and Khokhlov 1996). Supernovae of type I are explosions of hydrogen-poor degenerate material, and mark the endpoint of the evolution of a class of white dwarfs, probably accreting in BINARY SYSTEMS (see Branch (1998) for a review).

Type Ia

Independent analyses have teased out some of the systematic differences between these onetime 'standard bombs'. Hamuy *et al* (1996) found improved fits on including decline rate as a parameter in their analysis of the HUBBLE DIAGRAM. Riess *et al* (1996) included intrinsic color in their analysis as well, and found further improvements in the model fit (but see Branch *et al* 1996). The data strongly reject the hypothesis that either or both of these dependences appear by chance. Calibration of this standard candle was initiated by Sandage *et al* (1994) with their distance to the host galaxy of SN 1937C. Gibson *et al* (1999) use the reddening corrected Hubble relations of Phillips *et al* (1999) and obtain $H_0 = 68 \pm 6$ km s^{-1} Mpc^{-1}, significantly higher than the results of Saha *et al* (1996a, b, 1997).

Type II

A fundamental technique for distance determination in both expanding and radially pulsating objects is that pioneered by Baade and Wesselink, in which the angular size of the expanding photosphere is monitored by means of the associated flux and temperature variations, and the linear size is monitored by integrating the radial velocity variations.

Although not blackbodies, as Baade and Wesselink assumed, Type II supernovae have photospheres whose emissivity can be calculated. Distances are derived from a comparison of photospheric angular diameter and the time-integrated expansion velocity (Kirshner and Kwan 1974). In the work of Schmidt *et al* (1994) the expanding photosphere method (EPM) has been employed to $cz = 14\,600$ km s^{-1}.

There is no evidence that any empirical recalibration of EPM is required at present by the Cepheid data. EPM provides independent and consistent constraints on the Hubble constant, currently yielding $H_0 = 73 \pm 11$ km s^{-1} Mpc^{-1}.

Surface brightness fluctuations

Surface brightness fluctuations (SBF) in early-type galaxies result from the counting statistics of the number of stars in a galaxy encompassed by a detector pixel (Tonry and Schneider 1988). If N is the average number of stars in a pixel, and $\bar{f}$ is the average flux from a star, the average brightness in a pixel is

$$\mu = N\bar{f}. \tag{2}$$

Since the number in a pixel of fixed angular size scales with distance as r^2 and the flux scales as r^{-2}, this mean surface brightness is independent of distance. The local rms from pixel to pixel, however, is

$$\sigma = \sqrt{N\bar{f}} \tag{3}$$

and this scales as r^{-1}: the smoothness of otherwise identical galaxies is proportional to distance.

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

We can derive a distance from a measurement of both μ and σ, provided that we know the average luminosity $\bar{L}$ corresponding to $\bar{f}$:

$$\bar{f} = \frac{\sigma^2}{\mu} = \frac{\bar{L}}{4\pi r^2}. \quad (4)$$

The radial power spectrum of $\sigma/\sqrt{\mu}$ yields $\bar{f}$ for early-type galaxies in a relatively straightforward manner, although the presence of GLOBULAR CLUSTERS in these galaxies adds a source of noise and potential systematic error (Blakeslee and Tonry 1995). The quantity $\bar{f}$ has been measured at a number of wavelengths, and its behavior as a function of galaxy color is reasonably well understood (Worthey 1993, Pahre and Mould 1994, Ajhar 1993) in terms of giant branch systematics in stellar populations. It remains to calibrate $\bar{L}$, and this has been done by Tonry *et al* (1997). Recently it has proved possible to employ the resolution of HST's planetary camera (WFPC2) to measure surface brightness fluctuations to 7000 km s^{-1} redshift (Thomsen *et al* 1997, Lauer *et al* 1998, Pahre *et al* 1998). Ferrarese *et al* (1999) find $H_0 = 69 \pm 7$ km s^{-1} Mpc^{-1}.

Results from the HST key project

We collect the results from calibrating five secondary distance indicators in table 2. There is good consistency between the results from widely different techniques, suggesting that the Hubble constant indeed lies between 60 and 80 km s^{-1} Mpc^{-1}. The key project calibration is entirely based on the Cepheid period–luminosity relation. Combining the constraints from the first four entries in table 2 yields 71 km s^{-1} Mpc^{-1}. Correction for the rather shakily known chemical composition dependence of the period–luminosity relation decreases the key project estimate of H_0 by 4% to 68 ± 6 km s^{-1} Mpc^{-1}.

Table 2. The Hubble constant from secondary distance indicators.

Indicator	H_0 (km s^{-1} Mpc^{-1})	
Tully–Fisher	71 ± 8	Sakai *et al* (1999)
(D_n σ)	78 ± 10	Kelson *et al* (1999)
SBF	69 ± 7	Ferrarese *et al* (1999)
SNIa	68 ± 10	Gibson *et al* (1999)
SNII	73 ± 12	Schmidt *et al* (1994)
Key project	68 ± 6	Mould *et al* (1999)

We caution the reader against the conclusion that the uncertainty in H_0 can be estimated from the consistency of the results in table 2. Uncertainties such as the distance of the LMC affect *all* the entries in Table 2 systematically. Detailed distinctions between random and systematic errors have been made by Madore *et al* (1998), to which we refer the reader.

Cepheid independent methods

Gravitational lensing

At the time Blandford and Narayan (1992) reviewed the cosmological applications of gravitational lensing, the time delay for the prototype lensed QSO 0957+61 was still in dispute at the 30% level. A clear observational determination has now been made (Kundic *et al* 1998), leaving the accurate description of the gravitational potential of this lens as the principal source of uncertainty in the measurement of the Hubble constant from it. Finding a unique model of the mass distribution is in general a difficult task for a system to which a major galaxy, its perturbers and the common cluster halo can all contribute. Turner (2000) asserts that the model for 0957+61 is robust and that the resulting $H_0 = 64 \pm 13$ km s^{-1} Mpc^{-1} for $\Omega = 1$ represents 95% confidence limits. The cosmological geometry is not a major issue for this $z = 0.36$ lens, affecting H_0 by +7% if $\Omega = 0.1$.

Sunyaev–Zeldovich effect

The thermal bremsstrahlung luminosity of the hot gas in x-ray emitting clusters of galaxies is given by

$$L_x = 1.4 \times 10^{42} n_c^2 r_c^3 T_x^{1/2} \text{ erg s}^{-1} \quad (5)$$

where n_c is the number density in the cluster core, r_c is the core radius and T_x is the temperature of the gas.

The Compton effect of electron interactions with the microwave background radiation yields a temperature diminution of the radiation:

$$\delta T/T = -0.0128 n_c r_c \frac{kT_x}{m_e c^2}. \quad (6)$$

One may then solve for r_c, whose angular diameter is also observable. According to Birkinshaw (1998) the current best fit to the clusters observed to that date is for a Hubble constant of about 60 km s^{-1} Mpc^{-1}.

Do we live in a bubble?

Apparently lower values of H_0 from more distant probes of the expansion suggest a model with a locally low density of galaxies. There are, however, constraints on the hypothesis that we live in a bubble, which we should consider. These are the observational determinations that the expansion is linear on 100 to 1000 Mpc scales, such as the work of Sandage and Hardy (1973) on brightest cluster galaxies.

More modern demonstrations include supernovae at intermediate distances and extension of the Tully–Fisher relation to 15 000 km s^{-1} (Dale *et al* 1999). These results limit the difference between the global and local values of the Hubble constant to a few per cent. The rarity of low-density bubbles is also attested by the microwave dipole anisotropy on degree scales. Wang *et al* (1998) find a robust upper limit on the global deviation from the local 10^4 km s^{-1} sphere of 10.5% in H_0 with 95% confidence.

The future

The Hubble constant appears to be a quantity which is well defined on large scales. Homogeneity and isotropy suggest that we are measuring a property of the universe

Copyright © Nature Publishing Group 2001

at the current epoch and not some local *ad hoc* parameter. A number of projects therefore suggest themselves:

- Microarcsecond astrometry from space will allow us to measure the trigonometric parallax of the LMC (Shao 1999). A parallax based Cepheid PL relation would be a nearer-term goal, improving on the results of Hipparcos.
- Interferometric measurement of Cepheid angular diameter changes will yield geometrical distances to these standard candles.
- The key project distances to galaxies in that program are now capable of improvement with infrared cameras on HST. This will essentially remove remaining uncertainties arising from extinction.
- One-step distance measurements which avoid the classical extragalactic distance scale will be further developed. The astrophysical models which describe rich clusters and galaxy lenses at large distances need to be probed in more detail.
- Miyoshi *et al* (1995) have shown that H_2O masers orbiting a massive compact object and following a Keplerian rotation curve provide a remarkably good fit to the radial and transverse motions of the components in NGC4258. There is potential in this technique to achieve higher precision and greater distances.

Developments in the subject are logged by Huchra (1998).

Acknowledgments

I wish to acknowledge my fellow team members in the H_0 key project. Team members include Shaun M Hughes, Fabio Bresolin, Shoko Sakai, Barry F Madore, Robert Hill, Laura Ferrarese, Holland C Ford, Garth D Illingworth, Daniel Kelson, John A Graham, Nancy Silbermann, Lucas Macri, Randy Phelps, Brad Gibson, John G Hoessel, Mingsheng Han, John P Huchra, Anne Turner, Abhijit Saha, Kim Sebo and Peter B Stetson. We are grateful to Brian Schmidt and John Tonry for their contributions. Much of the work presented in this paper is based on observations with the NASA/ESA Hubble Space Telescope, obtained by the Space Telescope Science Institute which is operated by AURA Inc under NASA contract no 5-26555.

Universal Time (UT)

A measurement of time used for civil timekeeping and based on the Sun's daily apparent motion. It is the mean solar time of the Greenwich meridian at 0° longitude. Universal Time replaced Greenwich Mean Time in 1928. In 1955 the International Astronomical Union defined a number of categories of Universal Time with increasing accuracy. UT0, the least accurate, is based on the optical observations of star transits at various observatories and represents the initial values of Universal Time. These values differ slightly from each other because of the effects of polar motion. By correcting for polar motion, UT1 gives the precise angular coordinate of the Earth about its spin. UT2 derives from UT1 by taking into account annual changes in the Earth's speed of rotation. Coordinated Universal Time is the international basis of civil and scientific time and is used for broadcast time signals. It is obtained from an atomic clock that is set to remain within ± 0.90 s to UT. In this way, the solar time that is indicated by Universal Time is synchronized with atomic time.

Universe

The sum of everything that exists and of which we can be aware; the entirety of space. There is a semantic difficulty in talking about the universe; on the one hand, we define it to be 'everything', but it may be (a) that our universe is finite, yet unbounded; (b) that the accessible universe is only a small part of a much larger entity, most of which we cannot observe; or (c) that there exist other universes of which we are not 'aware'.

Universe: Simulations of Structure and Galaxy Formation

The current cosmogonic paradigm posits that structures in the universe (such as galaxies and clusters) originated from tiny density fluctuations generated around the time of the Big Bang and subsequently amplified by gravity. The precise origin of the primordial density fluctuations is uncertain. One possibility is that they were generated when the universe underwent a brief period of exponential expansion known as inflation, a tiny fraction of a second after the Big Bang. In the most successful model, the mass density of the universe is dominated by an exotic form of matter called cold dark matter which consists of elementary particles that do not make any contribution to the luminosity density of the universe. The predictions of this model have been set out extensively, using both analytic calculations and computer simulations, the latter having become increasingly important over the past 20 years. The build-up of structure in a cold dark matter universe is hierarchical: small-mass objects are the first to condense out from the expanding universe at early times (high REDSHIFT), whilst more massive objects (such as rich clusters) form later by repeated mergers of smaller objects. A remarkable confirmation of this framework was provided by the discovery, in 1992, of anisotropies in the temperature of the COSMIC MICROWAVE BACKGROUND radiation (CMB) by the DMR instrument aboard the COBE satellite. The amplitude of these anisotropies was within a factor of two of the extant theoretical predictions. Spurred on by the deep images of the sky produced by the Hubble Space Telescope, which show galaxies as they were when the universe was only about 10% of its present age, a great deal of effort is now being directed towards modeling the formation and evolution of galaxies within the setting of cosmological structure formation in the dark matter. The dissipative gas dynamical processes involved in GALAXY FORMATION make this a challenging task that can only be tackled using either idealized models or large amounts of supercomputer time.

The physics of galaxy formation

Studies of the dynamics of galaxies confirm a fundamental inference made 25 years ago from studies of the kinematics of stars within galaxies: on scales larger than galactic nuclei, the dominant physical interaction is gravity. Furthermore, it is now well established that the predominant source of gravity is dark matter, that is matter that does not emit detectable electromagnetic radiation. Dark matter is now routinely 'imaged' through the phenomenon of GRAVITATIONAL LENSING, the relativistic deflection of the light from distant galaxies as it passes near an intervening cluster of galaxies. Independently of the exact identity of the dark matter, the dominance of gravity leads directly to a general scheme for structure formation, first outlined by Landau and Lifshitz in the 1950s, rigorously developed by Peebles during the 1970s, and calculated in detail using computer simulations in the 1980s and 1990s. The key concept is the gravitational instability experienced by small matter overdensities in the expanding universe. Matter fluctuations present in the early universe grow in amplitude approximately as a power-law in time and eventually collapse to form self-gravitating objects.

The process of gravitational instability sets the scene for galaxy formation, the main physical ingredients of which are set out in figure 1. Although the precise details depend on the identity of the dark matter, under quite general conditions, galaxy formation is expected to proceed via a two-stage process originally outlined by White and Rees in 1978. First, gravitational instability acting on collisionless dark matter, results in the formation of self-gravitating dark matter haloes. Gas, initially well mixed with the dark matter, participates in this collapse, but it is heated by shocks to the thermal (or virial) temperature of the dark matter haloes. Second, the hot gas cools radiatively, on a time scale set by atomic physics, due to bremsstrahlung, recombination and collisionally excited line emission. The rate of cooling depends upon the density of electrons and atomic nuclei, and so it was most efficient at high redshift, when the universe was denser. (In practice, the heating and subsequent cooling of the gas may occur rapidly and chaotically, particularly in small galaxies.) Just prior to gravitational collapse, angular momentum is imparted on the generally aspherical perturbations by gravitational torques exerted by neighboring clumps, as proposed by Hoyle in 1948. Thus, the initial collapse generically results in the formation of a gaseous disk. Once the disk has become centrifugally supported, the material in it begins to fragment into stars by processes that are still poorly understood. In this simplified picture, the spheroidal components of galaxies form by mergers of disk galaxies which jumble up the stellar orbits, disrupting their organized configuration.

The scheme outlined above provides a natural explanation for why there are galaxies of two basic types: disks and spheroids. It also elegantly explains why there is a limit to the luminosity that galaxies attain at the present day. The most luminous galaxies form in the most massive dark matter haloes. These have only recently collapsed because, as is the case in most current models, the amplitude of mass fluctuations is smallest on large scales. At the high temperatures and low gas densities prevailing in recently formed structures, cooling is very inefficient and the gas has not had time to cool and fragment into stars over the lifetime of the universe. One problem of hierarchical structure formation models is that the number of low-mass haloes that form exceeds the number of faint galaxies seen in the local universe. However, a likely solution is that the feedback of energy into the cooled gas from early generations of stars will have acted as a self-regulating mechanism. This feedback prevents substantial star formation activity in shallow gravitational potential wells, thus causing most of the small-mass haloes to harbor extremely faint galaxies.

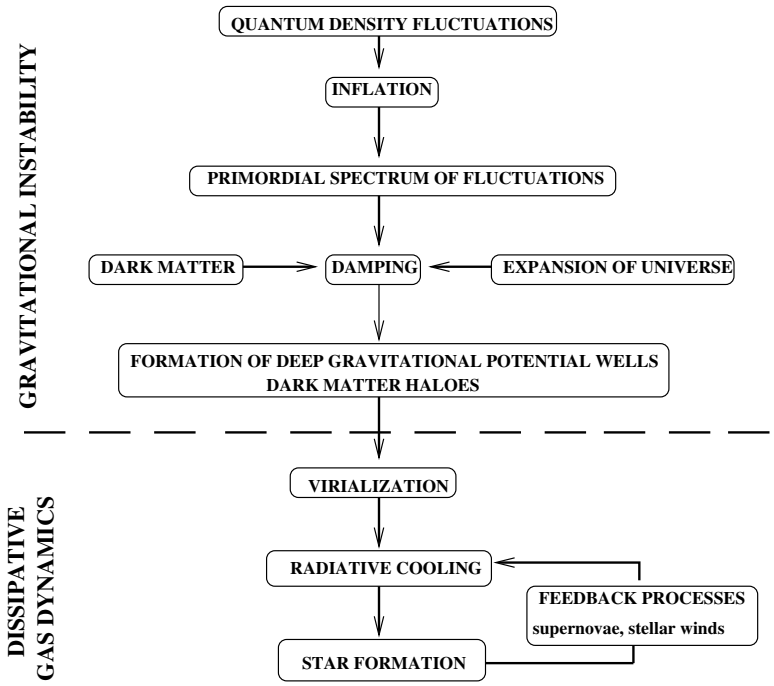

Figure 1. The ingredients of the standard model for the formation of galaxies and cosmological structure.

Cosmological structure formation

The processes of gravitational instability and collapse, gas cooling and star formation operate under quite general conditions. A quantitative theory of galaxy formation, however, requires that two key cosmological questions be addressed: (i) what is the origin of primordial mass fluctuations and (ii) what is the identity of the dark matter? Significant progress towards answering these questions was made in the early 1980s, as the result of a fruitful interaction between particle physics and cosmology.

The first influential idea of the 'New Cosmology' was proposed around 1980 by Alan Guth and extended by Andrei Linde. Searching for a solution to the 'magnetic monopole problem', Guth proposed that the universe had undergone a period of exponential expansion, or INFLATION, very soon after the Big Bang, triggered perhaps by the transition of a quantum field from a false to the true vacuum. Quantum fluctuations generated during this epoch would be swept across the event horizon and thus become established as classical ripples in the energy density of the universe. When they cross the horizon back again, their amplitude is independent of scale. Thus, the inflationary model predicts a scale-invariant power spectrum of primordial fluctuations, $P(k) \propto k$, with a Gaussian distribution of amplitudes. (More elaborate versions of the same idea can produce models whose power spectra have an exponent that differs slightly from unity.) The subsequent evolution of the fluctuations depends on the values of the cosmological density parameter, Ω_0, the Hubble constant, H_0, the COSMOLOGICAL CONSTANT, Λ_0, and the identity of the dark matter.

The second key idea from the 1980s concerns the identity of the dark matter. The abundance of the light elements (H, D, He, Li) produced during Big Bang nucleosynthesis agrees with astronomical data only if the present-day density of baryons is low enough for deuterium to form in at least the abundance measured in primitive gas clouds at high redshift. The baryon density required for this is about one order of magnitude smaller than the total mass density of the Universe inferred through a variety of tests. Thus, a fundamental conclusion is that the dark matter must consist of non-baryonic elementary particles.

Particle candidates for the dark matter are conveniently classified into 'hot' and 'cold' varieties, a nomenclature introduced by J R Bond around 1980. The prototype of a hot particle is a stable neutrino with a mass of the order of a few eV. (A single species of neutrino would give $\Omega = 1$ if its mass were approximately 30 eV and $H_0 = 50$ km s^{-1} Mpc^{-1}.) Examples of cold particles include the least massive stable supersymmetric particle, the neutralino, and the much lighter axion. Cold particles are often referred to as weakly interacting massive particles or WIMPs. There is a fundamental difference in the way in which galaxies are predicted to form in hot and cold dark matter cosmogonies, arising from the different damping mechanisms that affect the development of primordial fluctuations in the two cases. If the universe were dominated by massive neutrinos, then fluctuations below

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

some critical mass would be wiped out because the neutrinos move at relativistic speeds in the early universe and rapidly free-stream out of overdense regions. For a single neutrino of mass 30 eV, this critical scale corresponds to a fluctuation wavelength of

$$\lambda_c = \frac{2\pi}{k_c} = \frac{13}{\Omega h^2}\ \mathrm{Mpc} \qquad (1)$$

where we have parametrized Hubble's constant as $H_0 = 100h$ km s^{-1} Mpc^{-1}. The power spectrum decays exponentially for wavenumbers $k > k_c$.

In the case of cold dark matter, the damping of density fluctuations is much less severe. The free-streaming scale of cold dark matter is many orders of magnitude smaller than that of hot dark matter, and so this effect is not important. The most relevant damping process is the Mezaros effect, whereby oscillations in the radiation energy density stifle the growth of matter fluctuations. This situation persists until the energy density of matter dominates over that of the radiation, which occurs after a redshift of $1 + z_{eq} = 23\,900\Omega h^2$. The size of the horizon at this epoch is imprinted upon the cold dark matter power spectrum, marking the turnover of the primordial form, $P(k) \propto k$, to the damped fluctuation spectrum which asymptotes to $P(k) \propto k^{-3}$ at small scales.

In neutrino dominated models, the first structures that form are flat, pancake-like objects of mass comparable to that enclosed within the critical free-streaming scale, corresponding approximately to $10^{16} M_\odot$. These are objects of supercluster scale which must somehow subsequently fragment, in a 'top-down' fashion, in order for galaxies to form. Early computer N-body simulations of this process carried out by Frenk, White and Davis in 1983 showed that for a neutrino dominated universe not to exceed the level of clustering measured in the galaxy distribution today, galaxies would need to form at redshifts $z \lesssim 1$. Yet, it was already known at that time that quasars can have much higher redshifts than this and, today, we know that there is a large population of galaxies already established at $z = 3$–5. Thus, although rather appealing at first sight, neutrino dominated universes with Gaussian primordial fluctuations were soon abandoned.

The alternative, a cold dark matter universe, proved to be much more successful, as discussed, for example, in a series of papers in the 1980s based on N-body simulations, by Davis, Efstathiou, Frenk and White. The defining property of the fluctuation spectrum in a cold dark matter universe is that small-scale perturbations are preserved. Thus, subgalactic mass haloes are the first to collapse and separate out from the expansion of the universe. These haloes then grow, either gradually by accreting smaller clumps, or in big jumps by merging with other haloes of comparable size. The timetable for the formation of structure in a universe dominated by cold particles is hierarchical or 'bottom-up'—small objects form first, larger objects form later. The cold dark matter fluctuation power spectrum thus specifies completely the evolution of the merging hierarchy of dark matter haloes into which the baryons must fall in order to make the galaxies.

Currently, the most successful version of the cold dark matter model has around 30% of the critical density in cold matter and 70% in the form of a vacuum energy density or cosmological constant term, so that the universe has a spatially flat geometry. This model is in good agreement with a range of observational data: the amplitude of the angular power spectrum of temperature fluctuations in the cosmic microwave background (including the location of the first 'Doppler' peak), the abundance of clusters of galaxies ranked by their x-ray luminosity, the clustering of galaxies on large scales, and the expansion rate of the universe as deduced from the brightness of distant supernovae.

The recent detection of oscillations in neutrino flavour by the Super-Kamiokande experiment, which require the neutrino to have a non-zero mass, has rekindled interest in the possibility that neutrinos might, after all, make some contribution to the density of the universe. In order to avoid the problems faced by a universe dominated by hot dark matter outlined above, most of the mass in the universe must still consist of cold dark matter, with neutrinos providing only a minority contribution. Such 'mixed' dark matter models have not proved as successful at matching the data as the pure cold dark matter model. Another possibility for accommodating massive neutrinos is to replace inflation with a different mechanism for generating primordial density fluctuations. Tom Kibble suggested in the 1980s that TOPOLOGICAL DEFECTS IN COSMOLOGY might arise during phase transitions in scalar fields present in the early universe. Certain classes of defects, such as strings and textures, can act as seeds onto which matter gravitates, generating inhomogeneities in the mass density of the universe. These have the defining feature of being non-Gaussian. Unfortunately, modeling the formation of structure in defect models has turned out to be more complicated than in the Gaussian case because, amongst other subtleties, the properties of the defects themselves evolve with time. Defect models have not yet been explored with the same degree of rigor as the cold dark matter model. However, the current indications are that they have difficulties reproducing the spectrum of temperature anisotropies measured in the cosmic microwave background radiation. Thus, from a cosmological point of view, the oscillation data are best accommodated if the neutrino mass is very small (much less than 1 eV), so that neutrinos make a negligible contribution to the cosmic mass budget.

Computer simulations of galaxy formation

The remarkable developments of the past 15 years—the idea of cosmic inflation, the cold dark matter model, the discovery of ripples in the microwave background, and the observations of galaxies at high redshift—have laid down very solid foundations on which to build an understanding of galaxy formation. The 'initial conditions' for the evolution of the dominant dark matter component and its

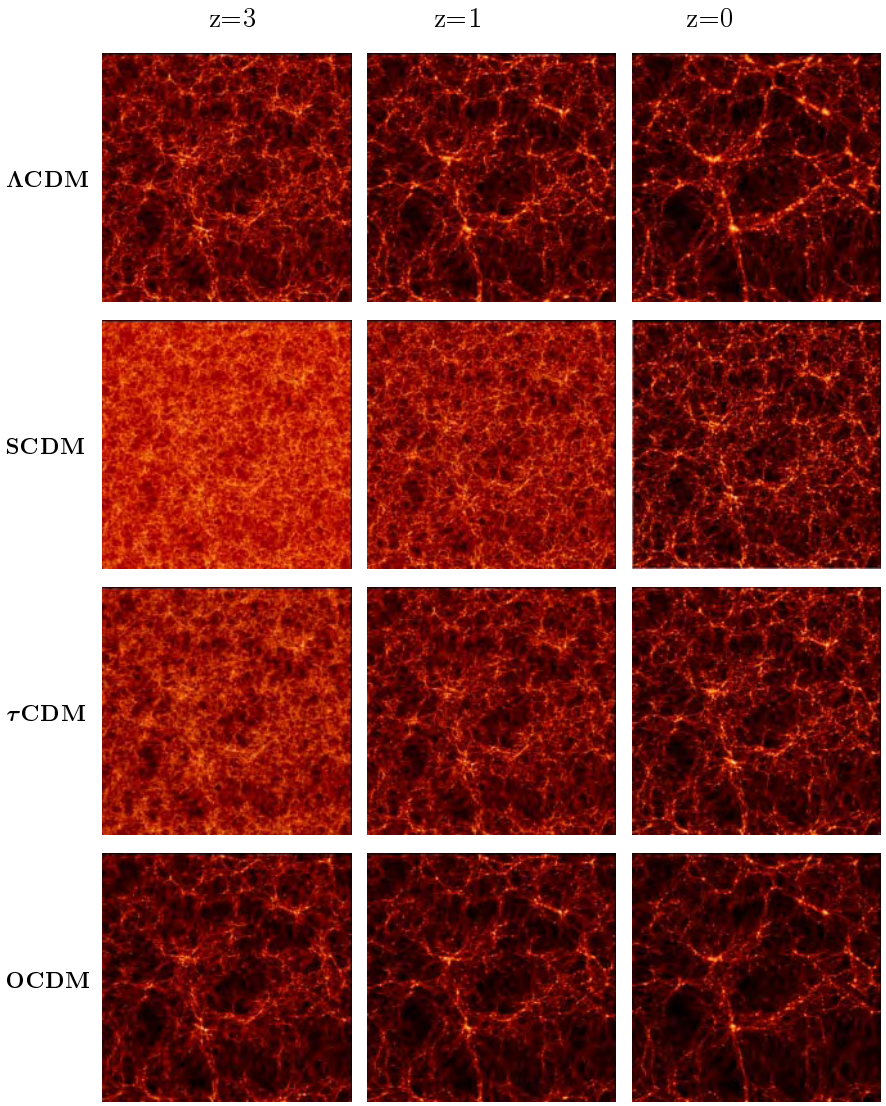

Figure 2. The formation of structure in N-body simulations of representative cosmological volumes of the universe. The intensity of the shading indicates the density of cold dark matter. Each row shows results from different versions of the cold dark matter model. The top row is a flat universe with $\Omega_0 = 0.3$ and a cosmological constant; the middle two rows are $\Omega_0 = 1$ universes, with different power spectra; the bottom row is an open universe with $\Omega_0 = 0.4$. The images, from left to right, show the evolution of structure in each model as a function of redshift. The present day corresponds to $z = 0$ while $z = 3$ corresponds to the epoch when the universe was approximately 15% of its current age. (Courtesy of the VIRGO Consortium for Cosmological N-body Simulations.)

subsequent gravitational evolution are well understood. Yet formulating an *ab initio* theory of galaxy formation and evolution over 10 billion years of cosmic history remains a tall order. The main stumbling block is our poor understanding of the behavior of cosmic gas—most probably a complex, dynamic, multiphase medium, of the physics of star formation, and of the feedback between the two mediated by winds from massive stars and supernovae explosions. The best way to address these issues is through extensive computer simulation and modeling.

The basis for present-day cosmological simulations is the N-body technique, which has been very successfully applied to modeling the evolution of collisionless dark matter. Using various computationally efficient methods, the computer solves the coupled equations of motion of N particles, interacting only through gravity, in the expanding universe. Progress over the past two decades has been driven mainly by dramatic improvements in the speed and memory of computers. By way of illustration, the early simulations of the cold dark matter cosmogony in 1985 employed 32 768 particles. In 1999, the largest simulations performed on massively parallel supercomputers (using essentially the same algorithms as

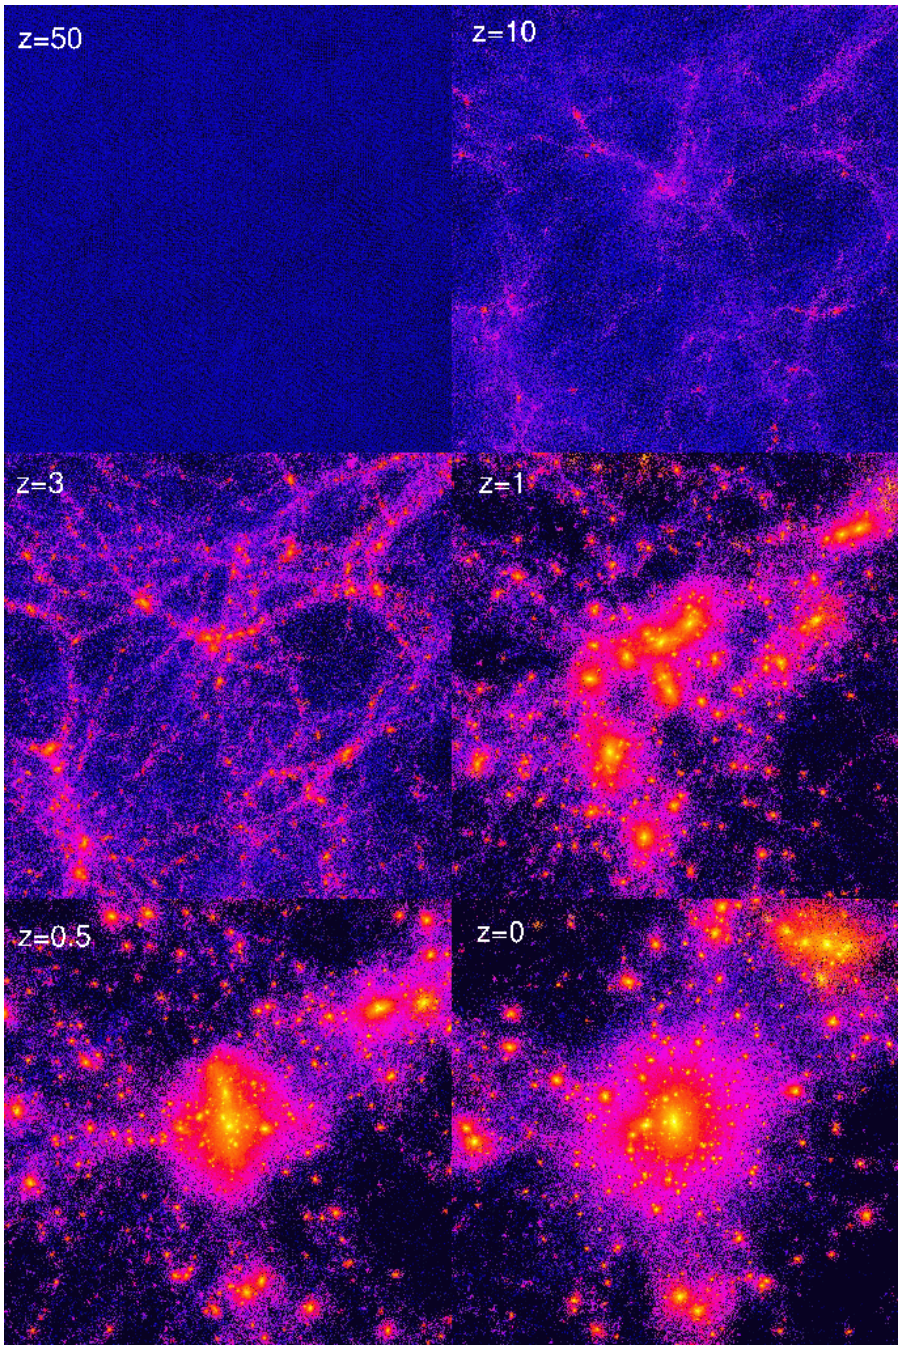

Figure 3. A high-resolution simulation of the formation of a single dark matter halo in a cold dark matter universe. The brighter colors indicate higher densities of dark matter. The sequence shows a series of snapshots of the evolution of the halo, at the redshifts indicated in the legend. The present-day halo displays a significant amount of substructure within its virial radius. (Courtesy of Ben Moore, Joachim Stadel, Tom Quinn and George Lake.) **This figure is reproduced as Color Plate 69.**

those of the 1980s) can follow the evolution of 10^9 particles.

Snapshots from simulations of representative, cosmological volumes are displayed in figure 2. This figure illustrates the evolution of structure in four versions of the cold dark matter model, differing only in the values of the cosmological parameters, Ω and Λ. At the present day, the dark matter is arranged in a complex network of voids, filaments and super-clusters (dubbed the 'Cosmic Web' by Bond, Kofman and Pogosyan). It is similar in all the sim-

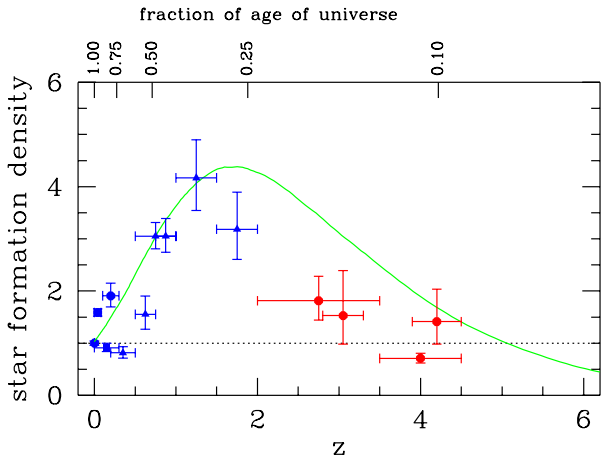

Figure 4. The star formation history of the universe. The curve shows the theoretical prediction for a cold dark matter universe, from the Durham semi-analytic model of galaxy formation. The points show a selection of recent observational determinations of the star formation rate density expressed in units of the present-day value.

ulations, partly because the amplitude of the initial fluctuation spectrum was adjusted so that all models would approximately reproduce the observed local abundance of hot, x-ray emitting clusters. (In addition, the initial fluctuations were set up with the same random phases in all the simulations, so that structures form at the same locations within each volume.) The development of structure proceeds at different rates in the different cosmological models. In those with a low value of Ω (top and bottom rows in figure 2), the formation of structure is essentially frozen at high redshift, whereas in the models with $\Omega = 1$, growth continues to the present. This merely reflects the fact that low-density universes expand more rapidly at late times, with the result that the expansion overwhelms the accretion of matter onto overdensities which lies at the root of their growth.

Simulations of sufficient size to resolve the internal structure and dynamics of dark matter haloes have recently become possible. The largest of these employ several million particles to model the formation of a single halo, revealing the existence of a rich substructure of lumps within the virial radius (figure 3). The simulations show that there is a remarkable uniformity in the density structure of dark matter haloes: over a wide range of scales, the spherically averaged halo density profile in follows a simple form proposed by Navarro, Frenk and White in 1996:

$$\rho(r) \propto \frac{1}{r/r_s(1+[r/r_s]^2)} \qquad (2)$$

where r_s is a scale length related to the density of the universe at the time when the halo formed. This functional form appears to be universal, independent of the choice of halo mass, power spectrum or cosmological parameters.

The N-body technique can be augmented with numerical hydrodynamic methods to model the evolution of gas subject to cooling and heating processes and coupled gravitationally to the dark matter. Two such methods are currently in use: Eulerian methods (including adaptive mesh refinements in some cases) and a Lagrangian scheme known as smoothed particle hydrodynamics. The two techniques have advantages and disadvantages, but so far the latter has proved to be the best suited to studying galaxy formation, because of the formidable dynamic range in thermodynamic quantities involved in the problem. At present, most progress has been achieved in modeling the physics of primitive gas clouds at high redshift, the so-called LYMAN ALPHA FOREST, detected observationally as absorption lines in the spectrum of distant quasars. The first simulations capable of following the evolution of gas to the present, with enough resolution to model the brightest galaxies, are now being carried out by various groups around the world. Currently, only a subset of the relevant gas physics, such as the shock heating of gas within dark matter haloes and its subsequent radiative cooling, are treated reliably.

A complementary technique for simulating galaxy formation *ab initio*, known as semi-analytic modeling, was developed in the 1990s by researchers at Durham and Munich. The main difference with the direct simulation approach is the abandonment of the ideal of solving the equations of hydrodynamics directly, in favor of a simple, spherically symmetric model in which the gas is assumed to have been fully shock-heated to the equilibrium temperature of each halo, from where its cooling and accretion onto the halo can be accurately calculated. This simplification speeds up the calculations enormously and has the added advantage of bypassing resolution considerations which are one of the main limiting factors of full hydrodynamic simulations. Phenomenological models of star formation, feedback and metal enrichment by supernovae are included in the semi-analytic program, through simple scaling relations. The semi-analytic machinery may be grafted onto haloes grown in a cosmological N-body simulation or onto haloes whose formation histories have been generated using a Monte Carlo approach. The models describe the entire star formation and merger history of the galaxy population. The free parameters of the model, which, perhaps surprisingly, are rather few in number, can be set by requiring a good match to a selection of properties of the local galaxy population, such as its luminosity distribution. This results in a fully specified model that provides an ideal tool for comparing the predictions of the cold dark matter theory with observations of the high redshift universe.

Confronting the high-redshift universe

The combination of direct simulations and semi-analytic modeling has revealed in detail the manner in which galaxies are expected to form in the cold dark matter model. The picture that emerges is one of gradual

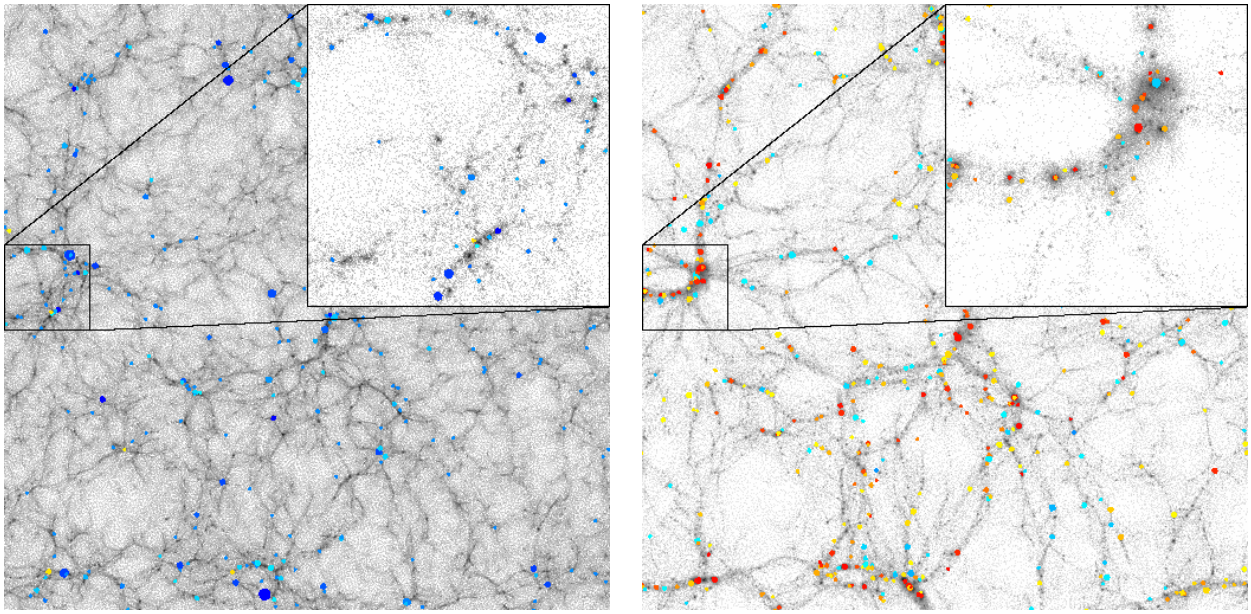

Figure 5. The evolution of clustering in the dark matter and galaxies. The left-hand panel shows an N-body simulation of a flat, low-density, cold dark matter universe with a cosmological constant, in a cube of comoving side $141h^{-1}$ Mpc, at $z = 3$. The right-hand panel shows the same simulation evolved to the present day. The gray scale indicates the density of the dark matter. Dark matter haloes in the simulation have been 'populated' with galaxies using a semi-analytic model of galaxy formation. The color of each spot reflects the color of each model galaxy, which is sensitive to the star formation rate. The size of the spot increases with the absolute luminosity of the galaxy. The inset shows the development of a cluster of galaxies. (Courtesy of Andrew Benson, Shaun Cole, CSF, CMB and Cedric Lacey.) **This figure is reproduced as Color Plates 70 and 71.**

evolution punctuated by major merging events that are accompanied by intense bursts of star formation and which trigger the transformation of disks into spheroids. Galaxy formation stutters into action around $z \sim 5$. Only a tiny fraction of the stars present today would have formed prior to that time. By $z \sim 3$, the epoch when galaxies isolated by the 'Lyman-break' technique[1] are observed, galaxy formation has started in earnest, even though only 10 per cent of the final population of stars has emerged. The midway point is not reached until about a redshift of 1–1.5, when the universe was approximately half of its present age. These theoretical predictions are shown in figure 4. Observationally, the star formation rate per unit volume can be inferred from the density of ultraviolet radiation, which is a measure of the number of high-mass, short-lived stars. Estimates of the star formation density based on data taken by ground-based telescopes and by the Hubble Space Telescope are shown as the points in figure 4. The major uncertainty in the interpretation of these data is the obscuring effect of dust, a modest amount of which has been allowed for in the models. But unless this effect turns out to be much stronger than anticipated, the theory and data in figure 4 suggest that we have now tracked most of the star formation activity, and the associated production of chemical elements, over the entire lifetime of the universe.

A second important prediction of the cold dark matter theory concerns the clustering properties of galaxies at high redshift. At the heart of the hierarchical clustering process lies the fact that galaxies tend to form first near high peaks of the density field because these are the first to collapse at any given epoch. This predilection for high-density regions is known as 'biased galaxy formation' (a term introduced by M Davis in 1985), because the distribution of galaxies offers a biased view of the underlying distribution of mass. An important consequence of biased galaxy formation is that bright galaxies tend to be born in a highly clustered state and remain so for long periods of time. The process of biased galaxy formation is illustrated in figure 5. The left-hand panel shows a snapshot of an N-body simulation of a cold dark matter universe at $z = 3$, whilst the right-hand panel shows the same simulation evolved to the present. The semi-analytic model of galaxy formation has been implemented in the dark matter haloes identified in the simulation at each redshift, in order to populate them with galaxies. Galaxies that are bright enough to be detected at $z = 3$ may be seen to form at the locations where the dark matter density (depicted by the gray scale) is highest. Observational confirmation of this clustering prediction came with the discovery that the population of galaxies at

[1] The so-called 'Lyman-break' galaxies are detected in passbands above the redshifted Lyman-limit at 912 Å and undetected in passbands below this limit; the strength of the Lyman-limit break is enhanced by absorption due to cold gas in the galaxy and in clouds along the line of sight.

$z \sim 3$ identified by the Lyman-break technique is about as strongly clustered as bright galaxies are today. The relative clustering strengths of galaxies and dark matter evolve quite differently. The right-hand panel of figure 5 shows that the dark matter is much clumpier today than it was at $z = 3$. On the other hand, the clustering pattern of galaxies has hardly changed over this long period of time. Galaxies today are found in a wide range of environments and have a clustering amplitude similar to that of the dark matter. This was not the case at high redshift when bright galaxies were much more strongly clustered than the dark matter—in other words, when they were very strongly biased.

The next steps

The two areas of agreement between theory and data highlighted here—the cosmic history of star formation and the clustering of high-redshift galaxies—are particularly noteworthy because they concern fundamental aspects of the theory. The broad agreement between models and data suggests that the main ingredients of a coherent picture of galaxy formation are now in place. These ingredients are: primordial Gaussian density fluctuations; collisionless, non-baryonic dark matter; gravitational instability; and the growth of galaxies by hierarchical clustering. There are justifiably high expectations for the next decade. The number of 10 m class telescopes is proliferating: the first of the four European Space Observatory 'Very Large Telescopes' came into full operation in 1999, the same year in which the Gemini and Subaru telescopes first saw light. Other large telescopes are under construction in the USA and Spain. The middle of the first decade of the new century should also see the launch of NASA's Next Generation Space Telescope, that will search for galaxies out to a redshift of 10, and ESA's Planck Surveyor, that will map the microwave background radiation with unprecedented precision. Towards the end of the decade, the 'Large Millimeter Array', sponsored by a major international partnership, is scheduled to come into operation in the Chilean desert. It will search for galaxy formation at high redshift and examine star formation in nearby galaxies in the still relatively unexplored sub-millimeter waveband. Ultimately, the cornerstone upon which much of modern cosmology rests is the idea that the universe is dominated by non-baryonic dark matter. Experiments under way in the UK, Italy and the USA stand a good chance of detecting it, if it really exists, within the next few years. This will no doubt count as one of the most exciting discoveries in the history of science. For their part, theorists will not be standing still. Increased computing power, more efficient algorithms and, above all, a better understanding of the astrophysics of galaxy formation, are likely to result in a pretty good imitation, by computer, of the processes through which galaxies in our universe formed.

Universe: Thermal History

HUBBLE's discovery of the expansion of the universe in 1929 revealed our beginning from a much smaller and much denser initial state (BIG BANG THEORY). Penzias and Wilson's discovery of the COSMIC MICROWAVE BACKGROUND radiation (CMBR) in 1964 implied further that just after creation the universe was a hot soup of the fundamental particles whose dynamics was controlled by the energy density of the CMBR.

The microwave radiation that A A PENZIAS and R W WILSON discovered is more precisely BLACK-BODY RADIATION characterized by a temperature of around 3 K. Because this black-body radiation fills space and its photons outnumber all other photons and known particles by a billion to one, it sets the average temperature of the universe. Of course, many hotter places exist in the cosmos—stars, planets and even the interstellar medium. As the universe expands its temperature decreases inversely as its linear size. While the temperature today seems unimportantly small, the fact that the universe still has a measurable temperature means that it was incredibly hot in the beginning.

The thermal history of the universe is thus the story of what happens when a tremendously hot and dense plasma expands and cools. Understanding the very earliest moments requires knowledge of the fundamental particles and their behavior under extreme conditions (high densities and temperatures). The connection between the inner space of elementary particle physics and the deep outer space of cosmology which plays such an important role in cosmology today was born with the discovery of the CMBR.

The known thermal history

The hot Big Bang cosmological model (see COSMOLOGY: STANDARD MODEL) provides an account of the universe from the hot soup of quarks, gluons, leptons and photons that existed before 10^{-5} s, when the transition from quarks and gluons to neutrons, protons and related particles occurred, until the present. During much of the time the universe was in a state of near thermal equilibrium; needless to say, the departures from thermal equilibrium are very important and make the universe an interesting place today! As the universe expanded, it cooled, $T \propto 1/R(t)$, where $R(t)$ is the cosmic scale factor which sets the size of the universe. As it cooled, layer upon layer of structure evolved, beginning with the neutrons and protons being produced from quarks culminating with the building of the largest structures seen today, the great walls of galaxies.

During its earliest moments, the temperature was the key to describing the state of the universe, because it sets the level of thermal particle energies. The thermal-energy scale $k_BT \sim 1$ MeV $(T/10^{10}$ K) determines when it is energetically favorable for the next layer of structure to form, and which particle species are present in great number. When k_BT was much greater than the rest mass of a particle, it and its antiparticle were easily produced in pairs and were present in the thermal soup in numbers comparable to photons. During the radiation era, the thermal-energy scale and age of the universe were related by: $k_BT \sim 1$ MeV $\sqrt{t\ (\text{in s})}$.

The soup of particles that existed at 10^{-5} s consisted of the up, down and strange quarks and their antiparticles; electrons, electron neutrinos, muons, muon neutrinos, tau neutrinos and their antiparticles; eight types of gluons and photons (the eight massless gluons are the carriers of the strong color force). The thermal-energy scale at this time was about 200 MeV ($T \sim 2 \times 10^{12}$ K), and the other quarks (charm, bottom and top) and the tau lepton were too heavy to be pair produced and were not present (any present would have annihilated). At even earlier times, when it was hotter, they (and possibly other particles) would have been present in great numbers too.

According to quantum chromodynamics (QCD), the theory of the strong color force, a phase transition from a quark–gluon plasma to hadronic matter occurred at a temperature of around 10^{12} K. Because of the increasing strength of the color force with distance, all particles with color (quarks and gluons) became confined in colorless quark triplets (neutrons, protons and other particles, known as baryons) and quark–antiquark pairs (pions, kaons and other particles, known as mesons). Collectively, the mesons and baryons are known as hadrons; the hadrons are the particles that experience the strong nuclear force.

At the end of the phase transition from quarks and gluons to hadronic matter, almost all the hadrons were too heavy to be pair produced. They could, of course, still annihilate, and as the temperature approached 10^{11} K annihilations had eliminated almost all of the hadrons. Were it not for the slight excess of baryons over antibaryons (whose origin is still a mystery, but see next section), nucleons (neutrons and protons) would have annihilated and disappeared too. The one additional nucleon for every billion or so antinucleons, left a few nucleons for every several billion photons without antinucleon partners to annihilate with. The primordial excess of baryons over antibaryons is responsible for all the ordinary matter that exists in the universe today.

At an age of about 1 s and temperature of about 10^{10} K, the primary constituents of the universe were photons, electron–positron pairs, and neutrinos and antineutrinos of all three species. There were also a few nucleons for every ten billion or so photons, about equally divided between neutrons and protons. Over the next 200 s or so, a sequence of nuclear reactions occurred out of thermal equilibrium and synthesized about 25% of the nucleons into ^{4}He. Trace amounts of D (a few parts in 10^5) and ^{3}He (about one part in 10^5) escaped being incorporated into ^{4}He and a tiny amount of ^{7}Li (a few parts in 10^{10}) was produced. The other 75% of the nucleons remained as free protons. This series of events is known as Big Bang NUCLEOSYNTHESIS (BBN). The rest of the periodic table was produced billions of years later by nuclear reactions in stars.

Big Bang nucleosynthesis occurred rapidly and at low density (around 10^{-2} g cm^{-3}), while the rest of the elements were cooked more slowly and at higher density (around 10^2 g cm^{-3} or higher) in stars and stellar explosions. This explains the great differences in the nuclear yields of the Big Bang and stellar nucleosynthesis. In particular, Coulomb barriers and the lack of stable nuclides of mass 5 and 8 prevented BBN from producing elements beyond ^{7}Li.

Big Bang nucleosynthesis provides the earliest test of the standard cosmology as well as a probe of conditions in the early universe. The fact that the pattern of abundances seen in the most primitive samples of the cosmos is consistent with its predictions is one of the experimental cornerstones of the standard cosmology. Further, the exact yields of the light elements, most especially deuterium, depend upon the baryon mass density; from recent measurements of the primeval deuterium abundance in high-redshift clouds of largely unprocessed hydrogen, we can infer that ordinary matter (i.e. matter comprised of neutrons and protons) today contributes between about 4% and 6% of the critical density. (The average density of the universe determines its curvature: a critical-density universe is spatially flat; a subcritical-density universe is open or negatively curved and a supercritical-density universe is closed or positively curved.) Because BBN 'weighs' all the ordinary matter at a simpler time, it provides the most accurate determination of the amount of ordinary matter. Today, baryons exist in many forms—bright stars, faint stars including white dwarfs and black holes, clouds of cold gas and of hot gas, and dust—and are more difficult to inventory. Thus far, only about one-third of the BBN-determined baryon abundance has been directly accounted for.

Light-element production also depends upon the ambient conditions in the universe, and Big Bang nucleosynthesis can thus also be used as a probe of the particle soup that existed then. For example, the existence of an additional neutrino species beyond the tau neutrino would have led to additional ^{4}He production, in contradiction to the observations. This argument against the existence of another neutrino species was put forth in the 1980s by David SCHRAMM and his collaborators and was confirmed by experiments at particle accelerators in the 1990s.

Two other important thermodynamical events took place during Big Bang nucleosynthesis. At a temperature of around 10^{10} K neutrinos and antineutrinos (all three species) ceased interacting with electron–positron pairs and decoupled from the electromagnetic plasma. Thereafter, they evolved independently of the rest of the universe, interacting only through gravity. Neutrino decoupling occurred because the decreasing particle energies and densities made neutrino interactions with other particles increasingly infrequent. When the temperature was around 10^9 K, essentially all of the electrons and positrons disappeared as pairs destroyed by annihilations were no longer replenished by thermal pair creation. The slight excess of electrons over positrons preserved the few electrons per ten billion photons required to balance the charge of the protons. The electron–positron annihilations raised the number of photons in the universe by a factor of 11/4 and heated the photons slightly relative to the neutrinos; thereafter $T_\nu = (4/11)^{1/3}T$.

The radiation era ended when the universe was around 40 000 years old and the temperature was about 10 000 K. At this epoch, called matter-radiation equality, the energy density contributed by matter (both baryons and exotic dark matter, more below) and that by relativistic particles (photons and three neutrino species) were equal. Thereafter, the matter density would exceed that of relativistic particles, growing in proportion to the linear size of the universe. (The matter density decreases as $1/R(t)^3$ due to the volume dilution effect of the expansion; the energy density of the CMBR decreases as $1/R(t)^4$, with the extra factor of $1/R$ arising because photon energies are redshifted with the expansion.) Today, the energy density of matter is about a factor of 4000 times larger than that of the energy density of photons and neutrinos.

The dawning of the matter era marked the beginning of the formation of large-scale structure in the universe (see also UNIVERSE: SIMULATIONS OF STRUCTURE AND GALAXY FORMATION). The small inhomogeneities in the distribution of the exotic matter that existed (spatial variations in the mass density at the level of about one part in 10^5) began growing through the attractive force of gravity; prior to matter–radiation equality the universe was expanding too fast for this to occur. Their tight coupling to photons prevented baryons from participating in this growth.

Shortly after the radiation era ended, at a time of around 400 000 years and a temperature of around 3000 K, two related and very significant events involving the radiation took place. The first was the transition from ionized matter to neutral matter (called 'recombination', which is paradoxical since neutral matter had not previously existed). As the temperature dropped below 3000 K neutral matter became thermodynamical favored, and all but a few ions combined with the free electrons to form neutral atoms (a residual ionization fraction of around 10^{-4} persisted thereafter because ions and electrons became too rare to find one another to combine to form atoms). When the universe became neutral, its opacity dropped precipitously (free electrons efficiently scatter light, neutral atoms do not), and matter and radiation decoupled. Photons streamed freely and have not scattered since; this important event is referred to as last scattering. Once baryons decoupled, they were rapidly pulled into the cosmic structures being formed by the gravity of the exotic dark matter.

The black-body character of the radiation, established by the hot, dense conditions in the early universe, was preserved by the expansion of the universe (the deep mathematical reason involves the conformal invariance of Maxwell's equations and the conformal nature of the expansion), albeit with a decreasing temperature, $T \propto 1/R(t)$). Today, this black-body radiation, which at last

scattering resembled the light emitted by the Sun today, has been redshifted to the microwave part of the spectrum. In 1996, the far infrared absolute spectrophotometer (FIRAS) instrument on the Cosmic Background Explorer (COBE) satellite made the most precise measurement of its temperature, $T = 2.7277 \pm 0.002$ K, and showed that any deviations from a perfect black-body spectrum are smaller than 0.005%. Because there is no other viable mechanism for producing such perfect black-body radiation, the spectrum of the CMBR is one of the experimental pillars of the hot Big Bang cosmology.

The radiation in the CMBR has not scattered since the universe was 400 000 years old, and so it provides a snapshot of the universe at a simpler time, when matter was still nearly uniformly distributed and stars, galaxies and clusters of galaxies did not exist. The variations in the intensity (or temperature) of the CMBR across the sky today map the two-dimensional distribution of matter at this time because variations in the mass density produce temperature variations of the same size. Thus, the temperature variations of a few parts in 10^5 measured by the differential microwave radiometer (DMR) on the COBE satellite and other balloon and ground-based experiments imply the existence of variations in the matter density of approximately the same size. This level of inhomogeneity is just what is needed to produce the large-scale structure seen today—provided that the bulk of the matter is exotic dark matter and not baryons (more below). The variations (or anisotropy) of the CMBR also encode a wealth of information about the early universe and how large-scale structure formed. Higher precision and higher angular-resolution measurements will be made by future experiments including NASA's MAP satellite (scheduled for launch in late 2000) and ESA's PLANCK SURVEYOR satellite (scheduled for launch in 2007).

Three cosmic seas of thermal neutrinos should be with us today. Just as with the CMBR, the expansion of the universe maintained their thermal (Fermi–Dirac) distributions with a temperature that has decreased inversely with the cosmic scale factor since they decoupled. Because neutrinos did not share in the energy release from the electron–positron annihilations, the temperature of the neutrino seas is predicted to be smaller than that of the photons, $T_\nu = 1.947$ K. If they can be detected, these neutrinos will reveal the universe as it was about 1 s after the beginning. However, because low-energy neutrinos interact extremely weakly with ordinary matter their detection presents one of the greatest challenges in all of science.

Beyond the standard cosmology: the very early universe

The earliest history of the universe (before 10^{-5} s) is still a mystery, but is under intense study. The motivation is twofold: the hope that events which took place may explain some of the most pressing cosmological puzzles. For example, the reason for the small excess of matter over antimatter, the explanation for the regularity seen in the universe, and the origin of the primeval density inhomogeneities. The second motivation is the possibility that the early universe can be used to probe fundamental physics more deeply than particle accelerators and other Earth-based experiments. At the moment, the discussion of the universe at times earlier than 10^{-5} s is speculative, both because of uncertainties about the microphysics needed to describe these early times and the absence of cosmological tests like Big Bang nucleosynthesis. In any case, the physics and the cosmology are of sufficient interest to merit the discussion of the possibilities.

On fairly firm ground, the discussion of the thermal history of the universe can be extended back to around 10^{-11} s when the temperature was about 10^{15} K. This was sufficiently hot that the thermal-energy scale exceeded the rest masses of all known particles. At this time the thermal soup should have included all the quark and lepton species, gluons, photons and the $W^{\pm}$ and Z^0 bosons, all in roughly equal abundance.

The state of the universe earlier than this is much less certain. The prevailing belief is that a phase transition occurred and restored the full symmetry of the $SU(2) \otimes U(1)$ gauge theory of the electroweak interactions. ($SU(2) \otimes U(1)$ is the mathematical symmetry that underlies the unified theory of the electromagnetic and weak interactions.) At low temperatures the symmetry between the weak and the electromagnetic interactions is not manifest: the electromagnetic interaction has long range, while the weak interaction has very short range because the mediators of the weak force, the $W^{\pm}$ and Z^0 bosons, are very massive. The symmetry is said to be spontaneously broken, by the Higgs mechanism. When the symmetry is restored, all of the force mediators become massless. If the Higgs mechanism is correct, then there is at least one more spin-zero particle species, the Higgs boson, whose rest mass is greater than about 100 GeV and probably less than 300 GeV. Its discovery would be a striking confirmation of spontaneous symmetry breaking, and thus the Higgs is at the top of the 'most wanted' list at all accelerator laboratories.

As successful as the electroweak theory is, it provides only a partial unification of the forces, leaving out the strong color force and gravity. One possibility is there are other levels of symmetry breaking and symmetry breaking phase transitions. The simplest idea, grand unification, unifies the color force with the electroweak force. Estimates for the temperature at which the grand unification phase transition might take place are even more uncertain, but are around 10^{29} K, corresponding to a time of about 10^{-39} s.

Another interesting feature of symmetry breaking is the possibility that the phase transition did not occur smoothly and that 'defects' are created. (Such defects are known to be produced in phase transitions in condensed matter systems: vortices and magnetic flux tubes.) These so-called topological defects are concentrations of energy: point-like magnetic monopoles, one-dimensional cosmic string and two-dimensional domain walls. The kinds of

Copyright © Nature Publishing Group 2001
Brunel Road, Houndmills, Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

defects that can be produced depend upon the symmetry breaking pattern. Thus far, the cosmology of topological defects has not been promising: monopoles should have been grossly overproduced, domain walls have disastrous cosmological consequences, and cosmic string, once thought to be a possible seed for the formation of structure in the universe, predicts a pattern of CMBR anisotropy that is inconsistent with the measurements.

A much more promising idea arising from the consideration of cosmological phase transitions is INFLATION. Inflation refers to an enormous burst of expansion which might have taken place very early on (probably earlier than about 10^{-32} s). Because of its potential to explain a number of the most fundamental and most puzzling features of the universe, inflation has been the dominant theoretical idea in cosmology over the past 15 years. It can account for the smoothness of the universe, the origin of the primeval matter inhomogeneity, the heat of the Big Bang, and the nature of the Big Bang itself. Originally inflation was thought to be driven by the latent heat (or false-vacuum energy) associated with a first-order phase transition. Most models of inflation no longer involve a phase transition, but instead rely upon the potential energy of a fundamental scalar field.

Besides inflation, the most compelling ideas of early-universe cosmology are particle dark matter and BARYOGENESIS. It has been known for more than 50 years that most of the matter that holds galaxies and clusters of galaxies together is not in the form of visible stars but is 'dark' (i.e. does not emit or absorb detectable radiation of any form; see DARK MATTER: ITS NATURE). For at least a decade it has also been known that the total amount of dark matter exceeds by more than a factor of three the amount of matter in the form of baryons as determined from Big Bang nucleosynthesis. Further, with the level of inhomogeneity measured by COBE, the observed large-scale structure can only form if there is exotic dark matter. These facts are strong circumstantial evidence for a new form of matter in the universe.

The most promising candidates for the dark matter are elementary particles that were present in copious numbers in the thermal soup early on and which failed to annihilate away because of the weakness of their interactions. Of all the possibilities considered, the three most attractive are neutrinos (if they have a small mass) and axions or neutralinos (if they exist). (The axion and neutralino are as yet hypothetical particles predicted to exist by theories that unify the particles and forces of nature.)

Baryogenesis is a higher-level analog of Big Bang nucleosynthesis: BBN explains how baryons come together to make nuclei and baryogenesis hopes to explain the origin of the excess of quarks over antiquarks that leads to the existence of ordinary matter. The idea is that particle interactions that violate matter–antimatter symmetry and the conservation of baryon number and which occurred out of thermal equilibrium produced a slight excess of quarks over antiquarks. When the quarks formed into neutrons and protons, this led to the excess of baryons over antibaryons needed to ensure the existence of the ordinary matter.

The weak interactions violate matter–antimatter symmetry at a small level and are also predicted to violate baryon-number conservation through subtle quantum effects. Moreover, baryon-number non-conservation is a generic prediction of grand unified theories. While the details are not currently understood, nor is there any experimental evidence for the non-conservation of baryon number, nonetheless baryogenesis is a promising framework for understanding how the crucial excess of matter over antimatter arose.

To date, superstring theory has been the most successful approach to the unification of gravity with the other forces. Superstring theory makes two generic predictions relevant for cosmology. First, the existence of a new symmetry of nature that relates fermions and bosons (supersymmetry), and second, the likely existence of additional spatial dimensions. Because the known particles of nature cannot be paired off as fermion–boson partners, supersymmetry requires the doubling of the number of fundamental particles. The superpartners, as they are called, are predicted to have rest energies of the order of 100 GeV. If correct, this implies a doubling of the number of particles in the primordial soup only occurs at temperatures greater than around 10^{15} K. The lightest superpartner, usually the neutralino, is stable or very long-lived and has a rest energy of order 100 GeV. As mentioned above, it is a prime candidate for particle dark matter.

If there are extra spatial dimensions they must be 'small' enough to have escaped detection or be otherwise hidden from us. Small here refers to their being curled up like the circular dimension of a straw. While many versions of superstring theory predict that the extra dimensions are exceedingly tiny—10^{-34} cm or smaller—some versions suggest that they might be as large as a millimeter in extent! The cosmological implications of extra dimensions are not well understood and raise a host of additional cosmological questions, for example the explanation for the size discrepancy between the familiar three spatial dimensions and the extra spatial dimensions.

Even if superstring theory does not prove successful in unifying gravity with the other forces and in providing a quantum description of gravity, 'interesting physics' should have occurred at times earlier than 10^{-44} s and temperatures greater than 10^{32} K. This is the Planck era, the epoch when quantum gravitational effects should have been extremely important and the classical description of gravity given by general relativity should have been inapplicable. It could be that the universe achieved a limiting temperature due to the exponentially growing number of particle species (also a prediction of string theory), or that space-time dissolves into a foam. Even by the standards of early universe cosmology, speculations about the Planck era are extraordinarily speculative.

Universität Radioastronomisches Institut, Bonn

An institute of the University of Bonn, Germany. Carries out research at infrared, radio and submillimeter wavelengths. Particular research interests are the interstellar medium and intergalactic medium, especially galactic halos, and dwarf galaxies.

The institute was responsible for the discovery of the x-ray halo around the Milky Way in 1991.

Although it has recently disposed of a 25 m radio telescope in the Eiffel Mountains, the institute has a cooperative agreement with the Institute of Physics, Cologne, to use KOSMA, a 3 m radio telescope on Gornergrat in Switzerland.

University Observatory, Ludwig-Maximilians-Universität

The University Observatory of Ludwig-Maximilians-Universität was founded in 1816. Astronomers who worked or graduated at the Munich Observatory include: Fraunhofer, Soldner, Lamont, Seeliger and Karl Schwarzschild. At present four professors and ten staff astronomers work here. Funding comes from the Bavarian Government, the German Science Foundation, and other German and European research programs.

Facilities include the Wendelstein Observatory in the Bavarian Alps with a 0.8 m telescope. The Observatory is also a partner in the Hobby–Eberly Telescope Project in Texas.

The Observatory's mission is to teach astrophysics at the Ludwig-Maximilians-Universität in Munich, to research astrophysics and instrument development for the Very Large Telescope (ESO), the Hobby–Eberly Telescope (Texas) and the Wendelstein Observatory.

Research specialties are stellar atmospheres and winds; binary stars; structure, formation and chemical evolution of galaxies; galaxy clusters; dark matter and gravitational lensing; plasma astrophysics.

For further information see
http://www.usm.uni-muenchen.de.

University of Crete Observatory

Based in Heraklion. Scientific activity is evenly distributed between theory and observation. Observational research has been undertaken using a small observatory on Mount Ida (Skinakas), and international facilities such as Arecibo and Effelsberg (radio), the ATO-Australia (optical) and Rosat (x-ray). The observational activities cover a wide range of objects including comets, supernova remnants, planetary nebulae, nearby galaxies, the Magellanic Clouds, dwarf galaxies, radio pulsars and the Earth's ionosphere and magnetosphere.

University of Hawaii Institute for Astronomy

The University of Hawaii Institute for Astronomy was founded in 1967 to manage Haleakala Observatory on Maui, and later, Mauna Kea Observatory, and to carry out its own program of fundamental research. Institute staff also make extensive use of spacecraft for astronomical research and planetary exploration. The Institute's main offices are located in Manoa valley, just off the University's main campus on Oahu. A research institute within the University of Hawaii (UH), the IfA has a total staff of approximately 200, including about 50 faculty staff.

The Institute is one of the world's leading astronomical research centers. Its broad-based research program includes studies of the Sun, planets and stars, as well as interstellar matter, galaxies and cosmology. Most IfA astronomers use the giant telescopes atop Mauna Kea and Haleakala. They also use space observatories, such as the Hubble Space Telescope and the Chandra X-ray Observatory, to make observations that cannot be made from the ground. In addition to doing research, some astronomers design and build new instruments to measure and analyse the radiation collected by the telescopes. Other IfA scientists develop theories which explain the observations made by their colleagues.

During the last 30 years, the State of Hawaii has become the most sought-after location in the world for the construction of large ground-based telescopes. The focal points for this construction are Mauna Kea (4200 m) on the island of Hawaii and Haleakala (3000 m) on Maui. The remarkable clarity, dryness and stillness of the air above these isolated high-altitude sites led to the commissioning by the University of Hawaii of the Mees Solar Observatory on Haleakala in 1963 and the UH 2.2 m telescope on Mauna Kea in 1970.

Haleakala is lower in altitude than Mauna Kea, yet when compared to other astronomical sites outside Hawaii, Haleakala is an excellent location for optical and infrared observations of objects in Earth orbit, solar observations, laser ranging and laser guide star experiments, and the whole range of night-time astronomical observations. The IfA's Mees Solar Observatory on Haleakala is central to the Institute's solar astronomy program. It is set in a naturally fine location for studies of the extremely faint radiation emitted by the solar corona and chromosphere. At sea level, these outer atmospheric layers of the Sun are normally obscured by light scattered by small airborne particles, such as dust or pollen. Mees is a perfect use of Haleakala, which means 'The House of the Sun'.

The Lunar Ranging Experiment (LURE Observatory) operated by IfA for NASA, measures the motions of the Pacific Basin and interior of Earth by bouncing laser beams off reflectors on satellites. It has also been used to bounce laser beams off reflectors left on the Moon by the Apollo astronauts.

Institute for Astronomy staff will receive a share of the observing time on the University of Tokyo 2 m 'Magnum' telescope and on the US Air Force 3.7 m Advanced Electro-Optical Systems (AEOS) Telescope, both of which are located at the Haleakala Observatory. Rocketdyne Technical Services is contracted by the US Air Force to carryout satellite ranging, surveillance and other developmental activities at the Maui Space Surveillance Site on land leased from UH at the Haleakala Observatory. Hawaiian students will share the use of the 2 m Faulkes telescope with students in the UK when it is installed in Haleakala Observatory in 2001.

The summit of Mauna Kea on the island of Hawaii houses the world's largest astronomical observatory, with telescopes operated by astronomers from eleven countries. The combined light-gathering power of the telescopes on Mauna Kea is fifteen times greater than that of the Palomar telescope in California—for many decades the world's largest—and fifty times greater than that of the Hubble Space Telescope.

In addition to developing its own research program, the IfA has provided the scientific impetus for the development of Mauna Kea into the world's premier site for ground-based astronomical observatories. More major telescopes are located on Mauna Kea than on any other single mountain peak, and Mauna Kea is widely recognized as offering better observing conditions for optical, infrared and mm/sub-millimeter measurements than any other developed site.

The success of the 2.2 m telescope led to proposals for the construction of several other telescopes on Mauna Kea by national and international organizations. By the end of the 1970s, there were three new 4 m class telescopes—the NASA INFRARED TELESCOPE FACILITY (IRTF), the UNITED KINGDOM INFRARED TELESCOPE (UKIRT) and the CANADA–FRANCE–HAWAII TELESCOPE (CFHT). Two of these telescopes are specifically designed to collect infrared radiation; the dryness of the atmosphere above Mauna Kea is particularly advantageous at these wavelengths.

The characteristics that make Mauna Kea a pre-eminent site for optical and infrared astronomy also make it an excellent site for measuring short-wavelength radio waves. In 1987, two submillimeter-wave observatories were completed just below the summit. The California Institute of Technology and the US National Science Foundation supplied the expertise and funds for the CALTEC SUBMILLIMETER OBSERVATORY (CSO). The JAMES CLERK MAXWELL TELESCOPE (JCMT) belongs to a consortium of the United Kingdom, Canada and the Netherlands. More recently, the Smithsonian Institution, in collaboration with astronomers from Taiwan, has built an array consisting of eight 6 m submillimeter antennas designed to work together as a single telescope.

The 1990s saw the construction of a new series of giant optical/infrared telescopes on Mauna Kea. The twin telescopes of the W M KECK OBSERVATORY are the largest optical/infrared telescopes in the world. Their 10 m diameter mirrors each consist of 36 hexagons whose positions are controlled by computer. Japan and an international consortium led by the United States

Dirac House, Temple Back, Bristol, BS1 6BE, UK

have built the Subaru and Gemini Northern Telescopes, respectively. Both of these telescopes contain thin meniscus 8 m primary mirrors, and are designed for both optical and infrared astronomy.

At a lower altitude, on the southern flank of Mauna Kea, is the Hawaii antenna of the Very Long Baseline Array, which is part of a 5000 mile wide system of ten 25 m radio dishes that work together as the world's largest dedicated full-time astronomical instrument.

As part of the agreement between these organizations and the University of Hawaii, astronomers at UH are entitled to 10–15% of the observing time on each non-UH telescope on Mauna Kea, in addition to full use of the UH 2.2 m and 0.6 m telescopes.

University of Tokyo, Institute of Astronomy

Founded in 1987, the Institute of Astronomy, University of Tokyo, is located at Ohsawa, Mitaka, Japan, 30 km west of central Tokyo. Its objectives are research and education in observational astronomy. It has a staff of 3 professors; 5 associate professors; 8 research associates, 2 technical support staff, 2 administrative officers and several part-time staff (secretary, catering etc). Its major facilities include Kiso Observatory (105 cm Schmidt telescope); two 60 cm submillimeter telescopes; 2 m IR telescope (in collaboration with the Physics Department). Research specialities: galactic and extragalactic radio astronomy; galactic center; extragalactic optical/IR observations; observational cosmology/formation and evolution of galaxies; infrared stellar physics.

The Institute is supported by an annual fund from the University of Tokyo (Ministry of Education) and science research aids from the Ministry of Education.

Its member organization (in joint ventures) is the University of Tokyo, Graduate School of Sciences

Unsöld, Albrecht (1905–95)

German astrophysicist, became professor at the University of Kiel, where he studied stellar atmospheres and the way that spectral lines were formed and shaped—the effects of abundances, radiation damping, Doppler shifts, electric fields and atomic collisions. He analysed the spectrum of the star Tau Scorpii, which he obtained on a visit to the Yerkes and McDonald observatories. This was the first detailed analysis of a star other than the Sun and yielded the physical conditions in the atmosphere of the star.

Uppsala Astronomical Observatory

The Uppsala Astronomical Observatory (UAO) is a department of Uppsala University (UU) with research, undergraduate, graduate and public education as its main objectives.

UU was founded in 1477, and preserved lecture notes show that astronomy was taught in the 1480s. Among well-known professors at UAO are Anders Celsius (1730–44), Anders Angström (1842–58), Gunnar Malmquist (1939–59), Erik Holmberg (1959–75) and Bengt Westerlund (1975–87).

Current research focuses mainly on galaxies, stellar astrophysics and solar system minor bodies and is characterized by the combination of theory and observations. Nowadays the observational material comes from large international facilities like ESO (EUROPEAN SOUTHERN OBSERVATORY) or space observatories like the HST (Hubble Space Telescope).

At UAO, about 70 km north of Stockholm, there is a 36 + 33 cm double refractor from 1893 currently used mainly for public shows and at Kvistaberg, 50 km south of Uppsala, there is a 135 cm Schmidt telescope from 1964.

Uranus

With an equatorial diameter of 51 118 km (at the 1 bar atmospheric pressure level), Uranus is the third largest of the planets in the solar system, slightly larger than the more distant NEPTUNE. However, because of its lower density (1.27 g cm^{-3} compared with 1.64 g cm^{-3} for Neptune), Uranus ranks fourth among solar system planets in mass at 14.54 terrestrial masses. Its characteristic blue–green appearance is due to a layer of clouds of methane ice in its upper atmosphere that is not present in the atmospheres of JUPITER and SATURN. This cloud layer and the overlying methane gas preferentially absorb the red portion of sunlight, resulting in the distinctive color. Prior to the flyby of Uranus by VOYAGER 2 in 1989, little was known about the rotational or other physical characteristics of Uranus (given in table 1).

Uranus has a ring system and many satellites. The rings were first detected from observations of stellar occultations as the narrow rings passed in front of distant stars, causing the observed light to blink out temporarily as viewed from Earth. Nine narrow rings were detected in this manner. Voyager 2 detected a tenth narrow ring, a broad diffuse ring closer to the planet, and tenuous dust rings scattered among the rest (see URANUS: RINGS).

Prior to 1986, only five moons of Uranus were known. Voyager 2 found an additional 10 (plus one identified in 1999 from Voyager images). Earth-based observations since 1986 have resulted in the finding of another five confirmed or probable moonlets much more distant from the planet. The satellites, known and suspected, are listed in table 3.

Uranus is the first of the non-naked-eye planets to be discovered. Observations of the closer planets (Mercury through Saturn) date back to antiquity, but Uranus was discovered by William Herschel in March of 1781 using his home-made telescope in the back yard of his home in Bath, England (see HERSCHEL FAMILY). Technically, at sixth magnitude, Uranus is marginally visible with the unaided eye. However, it was indistinguishable from background stars until Herschel's telescopic observations.

Table 1. *Orbital and physical characteristics of Uranus.*

Semimajor axis of the orbit	19.191 AU
Eccentricity	0.046
Inclination over the ecliptic	0.77°
Sidereal period	83.7474 yr
Mean orbital velocity	6.83 km s^{-1}
Equatorial diameter	51 118 km
Equatorial diameter relative to Earth	4.007
Polar diameter	49 946 km
Flattening	0.023
Mass relative to Earth	14.54
Mean density	1.27 g cm^{-3}
Surface gravity (at P=1 bar)	8.86 m s^{-2}
Surface gravity relative to Earth	0.906
Escape velocity	21.28 km s^{-1}
Sidereal rotation period	17.24 h
Inclination of equator to orbital plane	97.92¬∞
Albedo (visual geometric)	0.57
Albedo (bolometric Bond)	0.30
Main atmospheric composition	H_2 (83%), He (15%), CH_4 (2%)

The early observations

In the 200+ yr of observation since its discovery, there have been monumental changes in our understanding of the planets in general and of Uranus in particular. The first major change was a recognition that the solar system was much larger than previously supposed. Uranus was more than twice the distance of Saturn from the Sun; its discovery gave great impetus to searches for even more distant planets. Perturbations to the orbit of Uranus led to independent predictions by mathematicians John Couch Adams in England and Urbain Jean Joseph Le Verrier in France. On the basis of Le Verrier's predictions, Johann Gottfried Galle and his student Heinrich Louis D'Arrest found Neptune on 23 September 1846, the same day they received Le Verrier's prediction.

In the meantime, Herschel continued his observations of Uranus with a telescope, again of his own making and far superior to those available to other astronomers of his day. OBERON and TITANIA were discovered by him in 1787, less than 6 yr after the discovery of the planet. For more than 10 yr, no other astronomers were even able to confirm his findings. Herschel was convinced that other satellites must also exist, but in 40 yr of searching he found none, although some historians claim that he may have been the first to see UMBRIEL (four times between 1790 and 1801). Credit for the discovery of Umbriel and ARIEL is generally given to William Lassell, who reported their sighting in 1851 to the Royal Astronomical Society. MIRANDA was discovered by Gerard Peter Kuiper in 1948, using the 82 in reflector of the McDonald Observatory in Texas. The same instrument was used by Kuiper and co-worker D L Harris to discover Neptune's Nereid in 1949.

The orbits of the Urananian satellites provided the first evidence of the unusual tilt of the equator of Uranus relative to its orbital plane. Excluding Miranda and the irregular satellite discovered in 1997 and 1999, all other Uranian satellite orbits are within 0.4° of being coplanar with Uranus's equator. The actual tilt of the rotation axis of Uranus is 97.92°, although by International Astronomical Union convention, which specifies as the north pole that rotation pole which lies north of the ecliptic plane, the tilt is more properly designated as 82.08° with retrograde rotation. Much speculation has surrounded this unusual rotation of Uranus. One popular theory is that, during its early history, Uranus had a more normal tilt, but that during the latter stages of formation the planet was struck by an Earth-sized PLANETESIMAL, resulting in the present extreme tilt. The only other planets to exhibit more than a modest tilt are VENUS and PLUTO, which are 1–3 orders of magnitude smaller in mass.

It was the low reflectivity of Uranus at the red end of the spectrum which led spectroscopist R Wildt to propose in 1932 the presence of methane (CH_4) in the atmospheres of each of the gas giant planets of the solar system. The low densities of these giant planets had also led to the conclusion that the primary atmospheric constituent was hydrogen (H_2), but confirmation of that fact came from Kiess *et al.* in 1960. Formal detection of helium (He) in the atmosphere of Uranus first came from Voyager 2 in 1986. All other gaseous components of Uranus's atmosphere (above the cloud tops) constitute a combined abundance of much less than 1%.

By analogy with Jupiter, each of the other gas giant planets in the solar system was expected to have an intrinsic magnetic field. However, the strength and orientation of those fields and the associated radio emissions were not determined until Pioneer and/or Voyager spacecraft flew close to these planets. It was the monitoring of these radio emissions that enabled Voyager scientists to determine the rotation periods of Saturn, Uranus and Neptune (see also URANUS AND NEPTUNE: ATMOSPHERES, IONOSPHERES AND MAGNETOSPHERES).

Space exploration

The only space vehicle ever to fly close to Uranus was Voyager 2. This hardy spacecraft was launched in August 1977, flew by Jupiter in July 1979, Saturn in August 1981, Uranus in January 1986 and Neptune in August 1989. As of late 1999, Voyager 2 continued to send back useful data about the particle and magnetic field environment of the outer solar system. Voyager 2 provided high-resolution images of Uranus's atmosphere, the ring system and 16 of the 21 known satellites. In fact, 11 of the 16 moons it imaged were discovered by Voyager 2. Voyager 2 also determined the detailed composition of the atmosphere, confirmed the presence of a highly tilted and offset magnetic field and measured the rotation period of the planet's interior. In fact, more than 90% of all we know about Uranus came from the measurements made by Voyager 2 and the subsequent interpretation of those measurements.

No other space missions to Uranus are at present planned and funded. Nevertheless, continued improvements in Earth-based telescopes and techniques are now providing updates to some of the Voyager data, especially in the area of atmospheric studies (as well as in the discovery of the new satellites mentioned earlier). The present emphasis on smaller, faster, less expensive missions does not bode well for missions to Uranus or Neptune, each of which requires long flight times and concomitant higher space flight operations budgets.

Composition and structure

Like its larger counterparts (Jupiter, Saturn and Neptune), Uranus is composed primarily of the light elements hydrogen and helium. Even the somewhat heavier compounds, confirmed methane (CH_4) and suspected ammonia (NH_3) and water (H_2O), are composed largely of hydrogen. This dominance of light elements is reflected in the low densities of the gas giant planets and in the absence of distinct liquid or solid surfaces in the interiors of these planets. However, in contrast to Jupiter and Saturn, methane, ammonia, water and the heavier core materials are thought to constitute a larger total mass than the overlying hydrogen and helium. These measured or deduced characteristics are thought to be the consequence of the formation process by which these planets came to be. There are a number of competing theories about the nature of that formation process. Since each theory, if sufficiently developed, predicts outcomes that are generally dependent on the starting conditions, the measured or deduced characteristics can become both an effective discriminator between theories and a means of determining the starting conditions.

All formation theories have certain characteristics in common. For example, each assumes a decrease in temperature in the presolar nebula as a function of increasing solar distance. That temperature gradient in turn determines which compounds are solid at a given distance from the Sun and which are not. With more material from which to coalesce, it is likely that the planetary cores which formed from the coalescing solids were larger at the distances of the gas giants than for the Earth-like planets, enabling the gas giants to capture more massive atmospheres. Uranus and Neptune may be smaller than Jupiter and Saturn as a consequence of the solar nebula being less dense at these greater distances from the Sun. Perhaps the growth of Uranus and Neptune therefore lagged behind that of Jupiter and Saturn. If the Sun went through its T-Tauri stage when atmospheric accretion was more or less complete for Jupiter and Saturn, but incomplete for Uranus and Neptune, most of the remaining source material may have been swept away, and further growth of the planets would have essentially stopped. In that scenario, the cores of Uranus and Neptune would have occupied a much larger percentage of their interiors than would have been the case for Jupiter and Saturn. Jupiter and Saturn were therefore expected to more closely represent the mix of materials in the original solar nebula (and in the present-day solar atmosphere).

Actual measurements confirm the predicted higher relative abundance of methane in the atmosphere of Uranus than that of Jupiter, Saturn or the Sun. These numbers imply an enrichment of carbon (relative to hydrogen) in Uranus's atmosphere that is about 24 times as high as the C/H ratio in the Sun. Carbon enrichment was also noted for Jupiter (Galileo probe measurements) and estimated for Saturn, although to a lesser extent than for Uranus (as predicted). As in the other gas giants, photochemistry of methane in the upper atmosphere produces a suite of hydrocarbons, but only acetylene (C_2H_2) has been detected thus far. Water (H_2O) has also been detected in the upper atmosphere (Feuchtgruber *et al.* 1997); its presence reveals an exogenic source of the water, presumably micrometeoroid ablation.

Dirac House, Temple Back, Bristol, BS21 6BE, UK

Helium abundance relative to hydrogen is also higher for Uranus (and Neptune) than for Jupiter and Saturn. Strangely, the helium abundances for Uranus and Neptune coincide (within the uncertainties of the measurements) with that measured for the Sun. Jupiter's atmosphere is moderately depleted in helium relative to the Sun; Saturn's is strongly depleted, having only a scant 20% of the solar He/H abundance. At very high pressures (>3 million bar) in the interiors of Jupiter and Saturn, hydrogen is transformed into a liquid metallic state. It is possible, especially in the case of Saturn, that higher-density liquid helium droplets slowly sink through the liquid hydrogen owing to the force of gravity, thus depleting the source of helium to the visible atmosphere. No such mechanism can operate in the interiors of the smaller Uranus and Neptune.

The vertical temperature profile of Uranus below the 600 mbar level increases monotonically with depth at an adiabatic lapse rate. Voyager radio science occultation measurements detected the presence of a methane cloud deck near the 1 bar pressure level, where the temperature is near 80 K. This value is colder than the minimum temperatures in the atmospheres of Jupiter and Saturn; it is for that reason that no methane clouds are present in their atmospheres. Uranus's tropopause is located near 100 mbar, where the temperature is near the minimum value of about 50 K.

Extrapolation of measured atmospheric temperatures into the interior of Uranus at an adiabatic gradient would lead to a central temperature between 6000 and 10 000 K. Unlike the other three gas giant planets, Uranus appears to have little or no heat escaping from its interior to warm the upper regions of the planet. Whether that is a consequence of its extreme axial tilt or is due to insulating layering below the visible cloud deck is not known at present. Interior modeling yields central densities of between 4.5 and 9 g cm^{-3}, depending on whether or not there is a separate molten rocky core out to a distance of about 5000 km from the center. Such a model might have the larger density values at its center, whereas a relatively well-mixed massive core of molten rocky and icy material extending through most of the interior would have the lower central density value. The measured second-order gravity harmonic (J_2=0.003 343), combined with a rotation period of 17.24 h and an oblateness (polar flattening) of 0.023, tends to favor the well-mixed core.

Dynamics

With little or no discernible internal heat source, Uranus might be expected to have little atmospheric turbulence. Figure 1 depicts the planet Uranus as seen by Voyager 2. The left-hand view is true color; the right-hand view is a highly color and contrast-stretched version of the same image. It is apparent that essentially all atmospheric features are symmetric around the rotation axis whose positive pole is just left of and slightly below the center of the disk in these images. Zonal wind velocities were measurable for only a few latitudes on the planet, mainly because

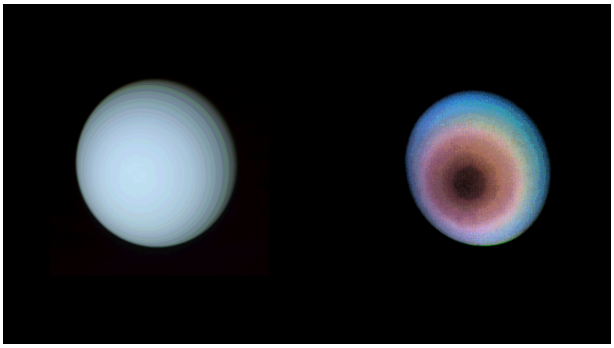

Figure 1. Uranus in true color (left) and contrast-enhanced false color (right). The planet's south (positive rotation) pole is left and below the center of the disk, at the center of the concentric patterns. Image from Voyager 2 courtesy of NASA Jet Propulsion Laboratory.

of the paucity of non-axisymmetric cloud features. Furthermore, only the illuminated southern hemisphere was visible. The data are best fitted with a latitudinal wind velocity in m s^{-1} of 200 (0.4cos$b$–cos3b), where $-90° < b < 0°$ is the latitude. This formula predicts a maximum prograde wind speed of about 240 m s^{-1} near –60° latitude, zero wind speed near –23° latitude and 120 m s^{-1} retrograde wind speed near the equator.

More recent images from the Hubble Space Telescope (HST) show greatly increased atmospheric activity for Uranus than was seen during the Voyager 2 flyby. Two color-stretched images, each including rings and satellites, are displayed in figure 2. The increase in atmospheric activity between 1986 and the 1997 HST images may be due in part to seasonal changes. During the Voyager 2 flyby, Uranus was near its southern sum-

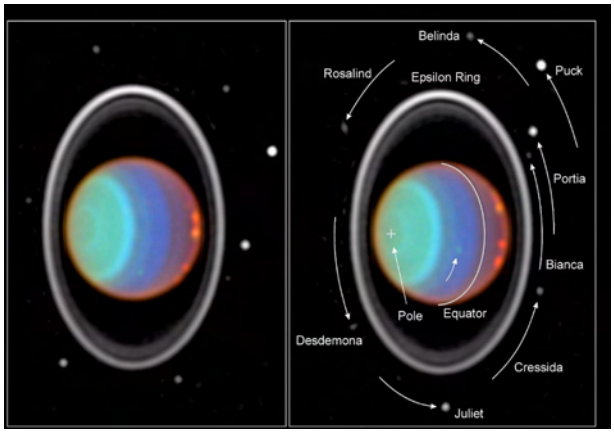

Figure 2. Uranus as seen from the HST's Wide Field Planetary Camera in 1997. The image on the right was taken later and shows the motion of satellites and atmospheric spots in the intervening time. The bright portion of the ring is the unresolved epsilon (ε) ring; the dimmer portion is a composite of several of the rings. Image from HST is courtesy of NASA Jet Propulsion Laboratory.

mer solstice (beginning of summer). In 2008 Uranus will reach an equinox, and all latitudes will be illuminated by sunlight. If the changes are due to seasonal effects, atmospheric cloud activity may be expected to increase until 2008 or beyond.

The temperature in the troposphere does not exhibit any north–south asymmetry despite the peculiar insolation pattern. The horizontal thermal structure shows little contrast other than shallow minima at mid-latitudes. The observed latitudinal dependence indicates that the zonal winds decay with height. Dynamical models suggest that the mid-latitude cool regions result from adiabatic cooling associated with upwelling in the troposphere and that poleward and equatorward flow occurs at upper levels.

Uranus's magnetosphere

The magnetic field of Uranus was first detected about 8 h before Voyager 2's closest approach to Uranus. Amazingly, the best dipole model of that magnetosphere indicates a magnetic dipole tilt of 58.6° and an offset from the center of the planet of 1/3 the radius of the planet in the direction of the unilluminated north pole. The high tilt and offset may indicate that the magnetic field is generated by electrical currents at fairly shallow depths within the liquid icy–rocky core. The dipole moment is more than a factor of 50 greater than the dipole moment of Earth's magnetic field, but, because of the larger size of Uranus, typical surface magnetic fields are of comparable magnitude for the two planets. The magnetic field of Uranus, like those of other planets in the solar system, is highly distorted by the solar wind. Its typical sunward extent is about 18 Uranian radii; the magnetic tail probably extends to thousands of radii downwind.

Ultraviolet auroral emissions were observed by Voyager 2 near the 44.2° north latitude magnetic pole. The auroral region was 15°–20° in diameter and is believed to be excited by electrons with energies of about 10 000 eV. A variety of radio emissions originating within the magnetosphere were detected. It was variations in the narrowband emissions near 60 kHz that enabled Voyager to determine that Uranus rotates once every 17.24 h. Detected charged particle species within the magnetosphere included mainly electrons and protons, although small amounts of ionized hydrogen gas (H_2^+) may have been present. It seems evident that the primary source of these particles is the extended hydrogen atmosphere of Uranus, which has a temperature of about 800 K at altitudes of 5000–7000 km above the cloud tops.

Rings

Uranus has 10 narrow rings with sufficient optical depth to block out starlight as they passed between a star and the Voyager spacecraft or groundbased observers. By far the densest and widest of these rings is the ε ring, which

varies in width from 20 to 95 km as its particles circle the planet. The other rings have typical widths of 1–10 km. The 'equivalent depth' of the ε ring (and most of the other variable-width rings) is constant; in other words, the same number of ring particles pass through the narrower portions of each ring during each orbit as through the wider portions of the same ring. Their narrow ring widths are the result of gravitational interactions with nearby satellites, which act as 'shepherds' to keep the ring material from spreading. The orbital characteristics of the narrow rings are given in table 2.

In addition to the 10 narrow rings, Uranus has a broad, diffuse and optically thin ring component seen in some of the Voyager 2 images. It is interior to the other rings, extending from a radius of about 37 000 to about 39 500 km from the center of the planet. During passage through the shadow of Uranus, Voyager 2 also snapped an image of the rings that is unlike any other taken at Uranus. In this unique geometry, forward-scattered sunlight brings out the optically thin dust bands that occupy much of the area between the ten narrow rings mentioned above. There is a lot of radial structure in these dust rings (see figure 3), little of it understood at present.

Satellites

Prior to 1999, Uranus had 17 known moons. The discovery of the five largest (Miranda, Ariel, Umbriel, Titania and Oberon) was discussed in the introductory material earlier in this article. Ten more (Cordelia, Ophelia, Bianca, Cressida, Desdemona, Juliet, Portia, Rosalind, Belinda and Puck) were discovered by Voyager in 1986. All of the moons discovered by Voyager orbit Uranus closer to the planet than the five 'classical' satellites. In 1997 Caliban was discovered by Brett Gladman and his associates. The same year Sycorax was discovered by Phil Nicholson and his associates. Caliban and Sycorax are more than 10 times as far from the planet as any of the previously known 'regular' satellites. Their orbits are retrograde, highly inclined and more eccentric than is true for the regular satellites.

In 1999, Erich Karkoschka found a previously undiscovered moon in images shuttered by Voyager 2 in 1986. This moon, which has an orbit almost identical to that of Belinda, was found in seven different Voyager 2 images. Based on a preliminary orbit, it is estimated that Belinda laps (passes) 1986U10 about once a month, a highly unusual circumstance.

Three more probable satellites of Uranus were sighted in 1999 by Gladman, J J Kavelaars and others. Orbits for these satellites are not yet well-determined, but they are probably all distant, irregular satellites. Their temporary designations are 1999U1, 1999U2 and 1999U3. In 2002 the discovery of another satellite was confirmed. Named S/2001 U 1, this brings the total number of confirmed Uranian moons to 21. S/2001 U 1 and five others like it have very irregular, eccentric orbits that do not share the same orbital plane as the larger moons of Uranus. Ranging in size from 10 to 20 km (about 6 to 12 mi), these moons are thought to be remnants of ancient collisions that occurred at the early stage of planetary formation.

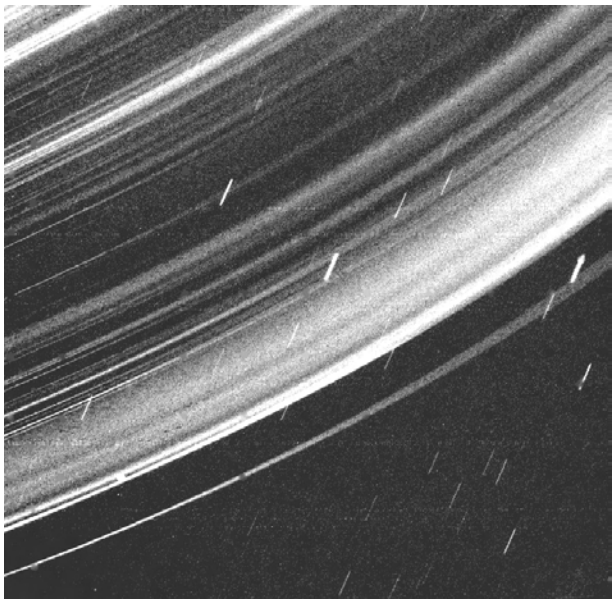

Figure 3. This long-exposure image from Voyager 2 was taken of the back side of the rings of Uranus during the spacecraft passage through the rings. The image was taken during rotation of the spacecraft and is therefore motion compensated at the left edge of the image, but the right side and the background stars are smeared. The outermost ring is the ε ring, but most of the other features seen are not identifiable with the narrow, optically thicker rings normally seen in backscattered light.

Uranus and Neptune: Atmospheres, Ionospheres, and Magnetospheres

Nearly the entire mass of URANUS and NEPTUNE consists of gas, much like the other gas giant planets Jupiter and Saturn. Therefore Neptune and Uranus might be regarded as essentially all atmosphere, although it is conventional to limit the definition to the outermost layers. In a tenuous outer layer of the atmosphere we find the ionosphere (see PLANETARY IONOSPHERES), where ultraviolet light and other radiations knock electrons loose from atmospheric molecules so that electrical currents can flow there. The magnetosphere begins even further out, where the atmosphere becomes so thin that collisions between its molecules are rare, and so they fly freely like orbiting satellites. In this region, the largest forces on electrons and IONS (electrically charged atoms or molecules) come from electric and magnetic fields, and so their motions are organized by the planetary magnetic field instead of planetary gravity (see PLANETARY MAGNETOSPHERES).

Most of what we know about Uranus's and Neptune's atmosphere and everything we know about their ionospheres and magnetospheres were learned from data collected during the close passes of VOYAGER 2 near Uranus in January 1986 and near Neptune in August 1989. Unfortunately this also means that it will be difficult to learn much more without more dedicated spacecraft encounters. As a result, our mental picture of these planets, especially Uranus, is dominated by their state during their Voyager flyby, and will become increasingly unrealistic as time progresses.

Atmosphere

Visually, Uranus and Neptune are blue planets, chiefly because of absorption of red light by atmospheric methane (CH_4). Uranus is virtually featureless, while Neptune has large but short-lived cyclonic storms that appear as spots. By tracking cloud features, strong east–west winds varying with latitude were found (especially at Neptune), indicating the presence of weather.

As tables 1 and 2 show, Neptune and Uranus are nearly twin planets about four times the size of the Earth and at much greater distance from the Sun. During the formation of the solar system, the material coalescing into the planets was extremely cold because of its distance from the Sun, and so most common gases (such as water, carbon monoxide and dioxide, ammonia and methane) were frozen. Because solid material more easily accumulates into planets than does gas, Uranus and Neptune incorporated much more of this material than did planets like the Earth, that formed in warmer regions. Once these frozen gases were incorporated into Uranus's and Neptune's warm interiors, they became gaseous again, but nevertheless were still bound by gravity. Because they were able to accumulate these more common materials, Uranus and Neptune grew much bigger than the terrestrial planets, and thus were massive enough to attract substantial amounts of the still-gaseous hydrogen and helium.

Thus by number of atoms, Uranus's and Neptune's atmospheres are mostly hydrogen with some helium and heavier gases, like the other gas giant planets and the Sun. Compared with the Sun, Jupiter and Saturn, however, Neptune and Uranus are highly enriched in oxygen, carbon and other elements heavier than hydrogen and helium. As a result, these heavy elements constitute at least 80% of Uranus and Neptune by mass. In these planets' atmospheres, carbon mostly combines with hydrogen to form methane, which is slowly broken down by solar ultraviolet light to form smog, just as on Earth (see PLANETARY ATMOSPHERES, EARTH'S ATMOSPHERE). Oxygen mainly joins with hydrogen to form water, which freezes out, leaving a dry upper atmosphere just as at Earth. Both of these condensible materials fall into the interior, where they are recycled back into gaseous water and methane.

Table 1. Useful Uranian constants, in units compared with Earth (⊕) and SI metric units.

Quantity	Earth units	SI units
Distance from Sun	19.18⊕	2.870×10^{12} m
Radius	4.01⊕	2.556×10^{7} m
Mass	14.54⊕	8.683×10^{25} kg
Orbital period	84.01⊕	2.651×10^{9} s
Rotation period	0.720⊕	6.206×10^{4} s

Table 2. Useful Neptunian constants, in units compared to Earth (⊕) and SI metric units.

Quantity	Earth units	SI units
Distance from sun	30.06⊕	4.497×10^{12} m
Radius	3.89⊕	2.476×10^{7} m
Mass	17.23⊕	1.024×10^{26} kg
Orbital period	164.8⊕	5.200×10^{9} s
Rotation period	0.673⊕	5.800×10^{4} s

Uranus One of Uranus's most remarkable traits is the direction of its rotation axis. Most planets' orbits lie in approximately the same plane, and their rotation axes (and the Sun's) are roughly perpendicular to this plane. Not Uranus; its rotational axis lies nearly in its orbital plane. It is believed that this great tilt was caused by a near-catastrophic collision at the time when Uranus was still forming out of infalling bodies, one of which must have been comparable in size with Uranus itself.

This 'tipped-over' orientation means that, part of the time, the Sun will be nearly overhead at Uranus's north or south pole. Because the rotational axis stays fixed in direction while Uranus orbits around the Sun, 1/4 of an orbit later the Sun will be over Uranus's equator. Therefore the differences between the solar heating during Uranus's summer and winter are much more extreme than at Earth, in addition to being much colder overall because

Dirac House, Temple Back, Bristol, BS1 6BE, UK

of Uranus's much greater distance from the sun. Despite these extremes of heat input, the temperature extremes are small, apparently because the atmosphere can equalize temperature differences by transporting heat.

Another anomalous trait of Uranus is its low rate of internal heat release. Heat slowly leaks out of the interiors of the other gas giant planets, at rates comparable with the planets' absorption of sunlight. However, Uranus' internal heat loss is undetectable.

Neptune Despite Neptune's greater distance, its temperature at its apparent surface is about the same as Uranus's. The reason for this is the heat release from Neptune's interior, which makes up for its relative shortfall of sunlight. In this aspect Neptune is a more typical gas giant planet than Uranus. Neptune's rotational axis is also more typical, in being roughly perpendicular to its orbit plane, so Neptune's seasonal variation of solar heating is much less extreme than Uranus's.

Ionosphere

Uranus's and Neptune's ionospheres are currently poorly understood, because of the limitations of the observations and gaps in theoretical knowledge. However, it appears that ionization due to solar ultraviolet and galactic cosmic rays is mostly responsible for maintaining the ionosphere, with enhancements from meteoritic impacts.

Magnetosphere

Uranus and Neptune have planetary magnetic fields whose surface intensity is the same order of magnitude as the Earth's field, but whose distribution is completely different. At Earth the field is oriented roughly north–south and its strength is roughly the same everywhere. Neptune's and Uranus's fields are much more variable in strength and direction.

Like Earth, Neptune and Uranus have AURORAS, which are glows created by electrons hitting the upper atmosphere where the magnetic field lines converge. At Earth auroras occur near the north and south geographic poles, but at Uranus and Neptune the magnetic poles lie at middle latitudes so that is where their auroras occur also.

Uranus The magnetosphere of Uranus is tilted once by Uranus's rotation axis and once again by the magnetic field's tilt with respect to the rotation axis. The charged particles in Jupiter's and Saturn's magnetospheres mostly rotate with their planets. At Earth charged particles flow in a kind of back-eddy opposite to the direction of the solar wind. At Uranus they do both at the same time, although this may change as Uranus's orbit carries it from Sun-over-pole to Sun-over-equator orientation.

Uranus's magnetosphere contains mostly atomic hydrogen ions (H^+), which probably come from Uranus' atmosphere.

Neptune The magnetic field of Neptune is also drastically tilted and offset with respect to the rotation axis. Despite Neptune's normal rotation axis orientation, charged particle trajectories are even more complicated here than at Uranus. Many of these trajectories exit the magnetosphere, so the density of ions in Neptune's magnetosphere is very sparse.

Neptune's magnetosphere contains mostly atomic hydrogen ions (H^+) and atomic nitrogen ions (N^+). These ions are probably derived from the atmosphere of TRITON, Neptune's large, icy moon. Triton's atmosphere is mostly molecular nitrogen with traces of hydrogen-bearing species such as methane.

Lower atmosphere and interior

Because Uranus and Neptune are gas giants, the distinction between atmosphere and interior is arbitrary. By convention the boundary between them is placed at a level where the pressure is 10–100 bar (1 bar $= 10^5$ N m^{-2} is about the pressure at the bottom of the Earth's atmosphere). This definition is based partly on observability and partly on the diminished effect of weather at that level.

Also by convention, the planetary radius is defined as the distance from the planetary center out to the level where the pressure is 1 bar at the equator. These are abbreviated as $R_U = 25\,559$ km and $R_N = 24\,764$ km, for Uranus and Neptune respectively.

Most of what is known of Uranus's and Neptune's interiors is derived from the slight departure of their gravity fields from spherical symmetry, detected by perturbations of Voyager's flyby trajectory. From these slight perturbations has been deduced an approximate density versus radius profile, which suggests the presence of rocky cores roughly half the size of Earth, representing about 0.1–1% of Neptune's or Uranus's total volume.

The properties of Uranus's atmosphere are summarized in figure 1, while Neptune's is summarized in figure 2. The number of molecules per cubic centimeter (number density) of each of the more important species is profiled versus altitude and pressure. The H_2 density is controlled by the temperature profile via the hydrostatic equation,

$$\frac{\mathrm{d}p}{\mathrm{d}r} = -\frac{mpg(r)}{kT(p)}$$

with p is the pressure, m the mass of an H_2 molecule, k Boltzmann's constant, $g(r)$ the acceleration of gravity as a function of altitude and $T(p)$ the temperature versus pressure profile. The densities of the other species are controlled by their interactions with the dominant H_2. The temperature profile is controlled by the balance of heat gain and loss, which is in turn controlled by the mechanisms by which heat is transported. The different temperatures seen at different levels result from different heat sources and transport modes dominating at different densities.

Both planets' tropospheres (from words meaning the region of changes; the lower atmosphere, where there

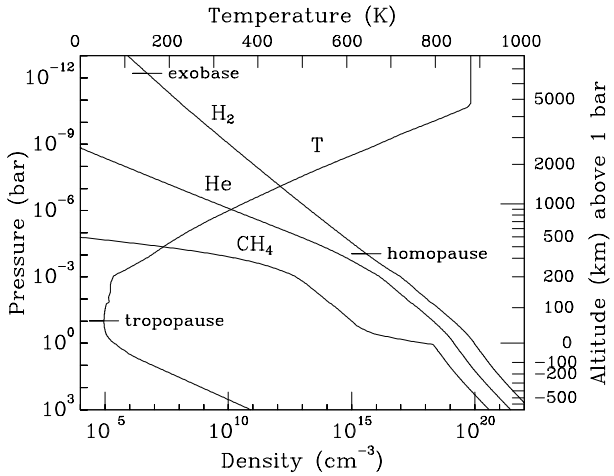

Figure 1. Profiles of temperature and density versus altitude in Uranus's atmosphere. The temperature (T) is read from the top scale, the densities (labeled by chemical symbol) from the bottom. Important boundary altitudes are marked on the profiles that determine them.

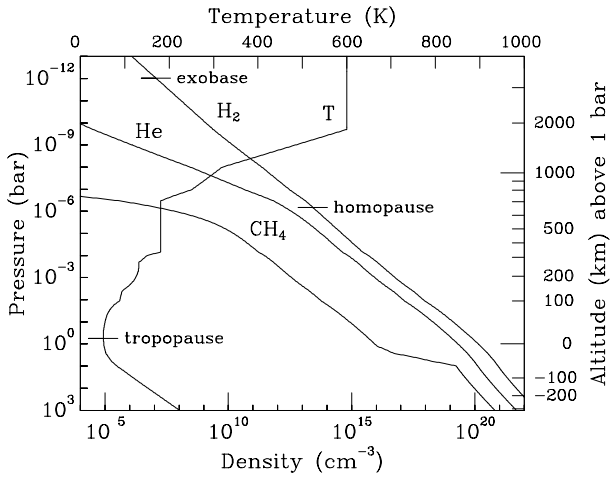

Figure 2. Profiles of temperature and density versus altitude in Neptune's atmosphere. The temperature (T) is read from the top scale, the densities (labeled by chemical symbol) from the bottom. The temperature profile is an approximation constructed to match the observations; its sharp bends are not real. Important boundary altitudes are marked on the profiles that determine them.

is weather) are very cold compared with Earth. Within the troposphere the dominant heat transport mode is convection, whereby heat is carried along with the gas as it rises and falls. Because the pressure changes with altitude, the gas is cooled by expansion as it rises and heated by compression as it sinks. Thus in the troposphere the temperature variation with altitude follows the adiabatic rate of change, that is, the rate at which a column of rising air would cool just as a result of expansion without heat exchange.

At Earth the vertical temperature profile is complicated by the condensation of water, but, in the colder Uranian troposphere, water condenses at a deeper level. At Neptune and Uranus the visible clouds are probably condensed methane. These clouds are located near the level of the sharp bend in the CH_4 profile just below the 1 bar level in figures 1 and 2. Above that level the ratio of CH_4 to H_2 density abruptly decreases because of methane condensation.

At the tropopause (the upper boundary of the troposphere, where the temperature stops falling with altitude), the temperature is about 50–52 K (much colder than liquid nitrogen) at both planets. The altitude of this transition point is marked on the temperature profiles displayed in figures 1 and 2. At this altitude the methane vapor pressure (at a given temperature, the pressure of vapor in equilibrium with its solid form; usually extremely temperature dependent) is at a minimum. Any methane abundance in excess of this pressure is frozen out and the resulting ice falls to lower altitude, which is why the CH_4 profiles in figures 1 and 2 show abrupt decreases there.

Uranus

The temperatures within Uranus's interior are probably high, but unknown. Heat constantly leaks out of the other gas giant planet interiors, and from the rate of heat loss a temperature versus radius profile necessary to maintain that loss can be calculated for those planets. Uranus's internal heat loss, by contrast, is too small to have been measured, so its internal temperature is unknown.

It may be that Uranus's interior is actually cooler than the other gas giants', perhaps because the collision that tipped Uranus over also stirred it enough to let its excess heat out. Another possibility is that the settling of denser materials has stabilized the interior so that hot gas does not rise and carry out heat, because even if the lower regions are hotter they would be compositionally denser and so not buoyant.

Neptune

Unlike Uranus, Neptune does have a measurable rate of heat loss, which is about 1.6 times as large as the rate of heat absorption from sunlight. From this heat loss rate, a temperature versus radius profile can be calculated, which is very near to an adiabat. The temperatures within the interior are high, reaching a maximum of probably about 6000 K at the center.

Upper atmosphere

Above the tropopause in each planet is the stratosphere, where the atmosphere is relatively stable (hence the name) because the temperature rises with altitude. Atmospheric stirring does not completely cease here, but it is greatly attenuated compared with the troposphere. In the lower stratosphere, the temperature profile is mainly controlled by the absorption and reradiation of heat absorbed from sunlight. The upper atmosphere is heated by a high-altitude energy source of unknown

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

nature. Because the energy is input at such low densities, no known component of sunlight or bombardment by magnetospheric charged particles can be responsible.

This heat is not reradiated from where it arrives, because H_2 and He are very poor radiators of heat and the more effective radiators, the hydrocarbons, are scarce here. Thus thermal conduction transports the heat down to the level where it can be radiated into space by the hydrocarbons. In order for conduction to carry the heat this far, the heat-source region's temperature must rise to high temperatures. From there up to the exobase (the atmospheric level above which atomic and molecular collisions are negligible), the atmosphere is roughly isothermal.

Because of the factor of m in the hydrostatic equation, atmosphere pressure diminishes with altitude at a rate proportional to m, the atmospheric molecular mass. When an atmosphere is a mixture of gases, atmospheric turbulence and other stirring mechanisms tend to keep the different gases mixed in equal proportions. Thus all gas densities decrease with altitude at the same rate, an average value which, at Uranus and Neptune, is about equal to the rate for H_2. However, above a certain altitude, where the mixing is not vigorous enough to keep the proportions uniform, each gas density decreases with altitude at its own individual rate. The point where this separation of rates begins is called the homopause, which is marked on figures 1 and 2. Notice the change in slope of the He and CH_4 profiles there, above which each constituent is decoupled from the others and so follows its own independent profile.

It is because of the rapid falloff of the CH_4 density compared with the lighter elements that the hydrocarbons are confined to lower altitudes, to which heat absorbed at high altitudes must be conducted before it can be radiated into space. Thus the level of the homopause helps determine the maximum temperature of the uppermost region of the atmosphere.

Uranus

The stratosphere of Uranus has been discovered to be unusually calm compared with the other giant planets, so that heavier gases such as helium and methane are not well-mixed with the hydrogen at higher altitudes. In other words, the homopause lies at lower altitude and higher pressure, about 10^{-4} bar in figure 1. Because of the low methane abundance at the higher altitudes where solar extreme ultraviolet light can penetrate and drive photochemistry, there are also lower abundances of the higher hydrocarbons such as ethane and acetylene there. Therefore there are fewer photochemically produced aerosol particles, or smog (an aerosol is a particle so small that it settles out of the air very slowly). As a result, Uranus's stratosphere is unusually clear for a gas giant, so that Rayleigh scattering (light scattering caused by spontaneous microscopic fluctuations of the air's density) is the dominant atmospheric opacity at wavelengths away from methane absorptions. At Earth, when opacity from water aerosols (clouds) is negligible, Rayleigh scattering is also important, turning the sky blue and sunsets red because of its λ^{-4} wavelength dependence.

Because the hydrocarbons lie so deep in the stratosphere, heat conducted from its source around 10^{-11} bar must travel a great distance. In order for conduction to carry the heat this far, the heat-source region's temperature must rise to about 850 K.

This high temperature inflates the upper atmosphere greatly, particularly the light atomic hydrogen component (a minor component at lower altitudes), so that it falls off slowly with altitude. Therefore even at the great altitudes ($1.64R_U \leq r \leq 2R_U$) of Uranus's rings, which are basically icy orbiting pebbles, the gas density is high enough to produce frictional drag. As with artificial Earth satellites, atmospheric drag causes Uranus's ring particles to gradually lose their orbit-maintaining momentum until eventually they fall vertically into the troposphere. Because the ratio of gas drag to particle inertia is largest for the smallest ring particles, Uranus's inflated atmosphere selectively removes the finest ring particles. The steady shrinkage of ring-particle orbits, piling up against the repulsive perturbations of larger orbiters with slower orbital decay, may be part of the reason that Uranus's rings are a series of very thin concentric bands, in contrast with the nearly continuous disk that constitutes Saturn's rings.

Neptune

The upper atmosphere of Neptune is much more vigorously mixed than is Uranus's, as shown in figure 2 by its higher homopause altitude (at around 10^{-6} bar instead of 10^{-4} bar as at Uranus). For this reason methane and other hydrocarbons are found at significant densities much higher in the atmosphere at Neptune, as is also evident in figure 2. Neptune's degree of atmospheric mixing is more typical of the other giant planets, Jupiter and Saturn, than is Uranus's.

Probably because the hydrocarbons reach higher in the atmosphere, the heat flow from Neptune's high altitude heat source (not well defined, but probably at no higher an altitude in pressure units than at Uranus) has a shorter distance to travel before it can be radiated into space. Therefore the hot uppermost regions of Neptune's atmosphere, at about 550–650 K, do not reach as high a temperature (about 850 K) as Uranus's does.

Ionosphere

Ionospheres are formed by ionizing radiation and represent a balance between the ion production rate and the recombination loss rate. Because both the recombination loss rate and the atmospheric opacity to ionizing radiation are proportional to gas density, which increases rapidly with depth in the atmosphere, ionospheres typically have sharp lower boundaries. The upper part of the ionosphere, however, typically decreases upwards at an exponential rate determined by the local atmospheric temperature. This rate has been measured for

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Neptune's and Uranus's ionospheres and is about right for H^+ ions.

In addition to this smooth variation, thin layers of higher electron density were observed in Uranus's and Neptune's ionospheres. It has been conjectured that these are transitory effects of meteor showers, which are observed to create ionization in Earth's atmosphere. These thin layers are at the bottoms of the two ionospheres, which lie at about 1000–2000 km above 1 bar at Uranus and about 500–1000 km at Neptune.

Magnetosphere

The magnetosphere is the region outside a planet's exobase, where the planetary magnetic field is strong enough to deflect the solar wind. On the upwind side, the pressure balance between field and wind creates a roughly parabolic boundary, called the magnetopause, with nose distance about $20R_U$ upstream at Uranus and $25R_N$ at Neptune. This boundary envelops its associated planet and extends downstream in a wake many tens of planetary radii long. Outside of this boundary is a roughly hyperboloidal bow shock standing in the highly supersonic solar wind.

The inner boundary of the magnetosphere is effectively its planet's exobase, below which collisions with atmospheric molecules control charged-particle motion. However, atmosphere–magnetosphere coupling can extend more deeply than the exobase, as magnetic-field-aligned currents can flow into the ionosphere, across to other field lines and back out into the magnetosphere. It is this coupling that drives much collective magnetospheric motion.

The magnetosphere encompasses a wide range of phenomena, described in their individual sections (see figures 3 and 4). Because of the long-range coupling present in the magnetosphere, its seemingly independent phenomena mutually interact more than is the case in the neutral atmosphere.

Plasma

PLASMA is a gas which contains significant numbers of ions and electrons, so that it conducts electricity at least along the magnetic field, and often perpendicular to it as well. The plasma at both Uranus and Neptune was composed of ions and electrons with kinetic energies covering Voyager's entire range of measurement, from 10 to about 10^7 eV (1 eV $= 1.6 \times 10^{-19}$ J is a particle kinetic energy equivalent to a temperature of about 8700 K). Plasmas in different energy ranges behave differently, so we discuss them separately.

The high-energy ($\geq 10^5$ eV) plasma at both planets is extremely sparse and forms radiation belts similar to those at Earth. It diffuses inwards through the magnetosphere, so that its absorption by satellites and rings creates decreases in density that were observed by Voyager. A few faint rings and satellites were discovered in this way. When these energetic particles strike icy satellites and ring particles, hydrogen and oxygen atoms are ejected.

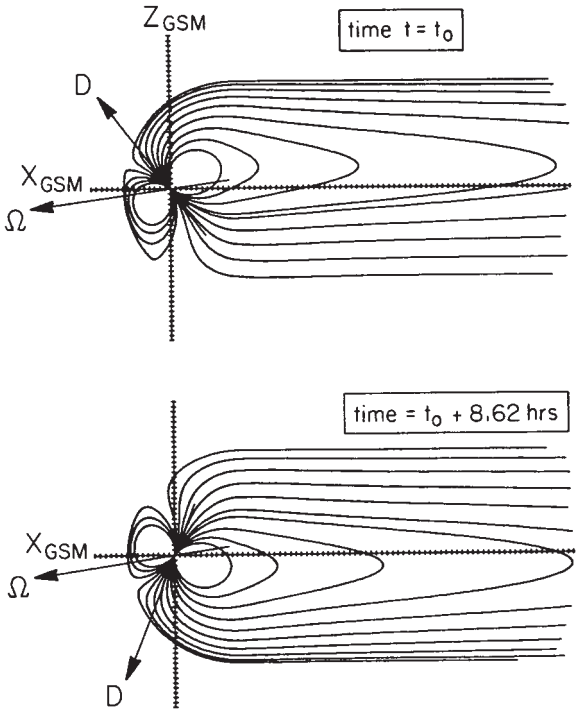

Figure 3. Diagrams of Uranus's magnetoshere. The curved lines depict the magnetic field as it is confined within the magnetopause. The arrow labeled Ω is Uranus's axis of rotation, and is fixed in space. The arrow labeled D is the magnetic dipole axis and rotates with the planet. The two diagrams show the magnetosphere at half-rotation intervals. The axis labeled X_{GSM} points toward the Sun. (Figure from Voigt *et al* 1987 *J. Geophys. Res.* **86** 15 337.)

The low-energy ($\leq 10^4$ eV) plasma drifts through these magnetospheres on paths determined mostly by the electric and magnetic fields. Both the rotation of the planets and the interaction of the solar wind with the magnetospheres create electric fields that fluctuate in time as well as space. In the following, we describe what is known of the behavior of the low-energy plasma.

Uranus. Uranus's magnetospheric plasma is rather tenuous and consists almost entirely of H^+. It appears to originate from Uranus's atmosphere, because if it came from the icy satellites there would also be O^+, which is not observed. It drifts Sunward as at Earth, but because of the pole-on configuration simultaneously co-rotates with Uranus. However, the co-rotation does not interfere with the plasma drift, as it does in the Earth's plasmasphere, because the rotation occurs about an axis parallel to the drift.

As the plasma drifts toward (away from) Uranus, it sees an increasing (decreasing) magnetic field strength which compresses (expands) the plasma and heats (cools) it drastically. Thus there is a plasma adiabat in the

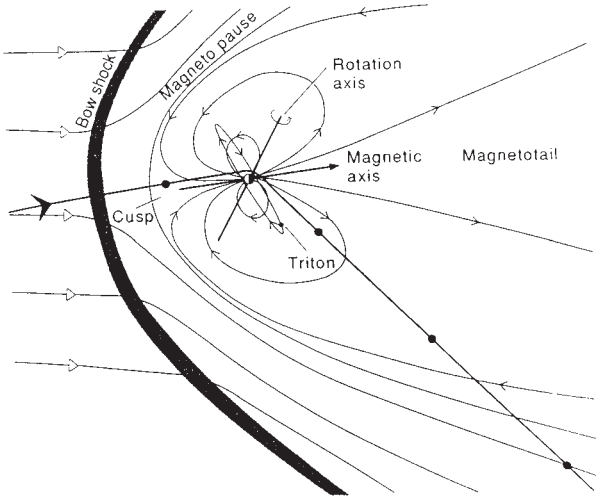

Figure 4. Diagram of Neptune's magnetosphere, showing its components. The curved lines with triangular arrowheads depict the solar wind flow deflected around the magnetopause. Those with V-like arrowheads are magnetic field lines, except the one labeled 'Triton', which is Triton's orbit. The line with the full dots is the trajectory of the Voyager flyby. (From Schulz *et al* 1995 Magnetospheric configuration of Neptune *Neptune and Triton* ed D P Cruikshank (Tucson, AZ: University of Arizona Press). Copyright © 1995 by The Arizona Board of Regents. Reprinted by permission of the University of Arizona Press.)

magnetosphere just as there is a gaseous adiabat in Uranus's interior.

The plasma consists of a number of components, which are distinguished by their temperatures. Because of the adiabatic drift compression, their densities and temperatures are best compared by referral to a standard distance from the Uranian magnetic dipole. Two low-energy populations are known; a warm plasma (0.5 cm^{-3} and 10 eV at $5R_U$) and a hot plasma (0.3 cm^{-3} and 1000 eV at $5R_U$). The warm plasma drifts by Uranus without much change, but the hot electrons continually lose energy (relative to their adiabatic temperature) as they approach Uranus. The hot ions also abruptly disappear inside approximately $5R_U$, as though their drift paths were avoiding Uranus.

Neptune. Neptune's magnetospheric plasma is very tenuous and consists mostly of H^+ and N^+ ions. Its source appears to be the atmosphere of Triton, because of the presence of N^+ ions. In addition, a measure of the plasma density, corrected for compression by the magnetic field, appears to decrease as Neptune is approached. If Neptune were the source, the plasma density measure would increase towards the planet instead.

The decrease of plasma density measure towards Neptune is due to loss of some of the plasma to collisions with the atmosphere as the charged particles bounce back and forth along the magnetic field lines. Unlike the case of the aurora, where high-energy (10^4 eV or more) charged particles from far out in the magnetosphere hit the atmosphere near the magnetic poles, this plasma loss refers to low-energy (tens of eV) plasma on field lines near the planet that is impacting the atmosphere far from the magnetic poles.

The motion of Neptune's magnetospheric plasma is complex and not completely understood. Neptune's spin axis is roughly perpendicular to its orbital plane, just as it is at Jupiter and Saturn, where magnetospheric plasma rotates with the planet. However, the large tilt of the magnetic field results in Neptune's magnetic dipole alternating between states pointed at the Sun and perpendicular to the Sun–Neptune line as Neptune rotates. As a result plasma motions in Neptune's magnetosphere fluctuate as Neptune rotates. As at Uranus, plasma motion is part Sunward back-eddy and part co-rotation.

Aurora

Auroras are regions where the atmosphere glows because of bombardment by high-energy charged particles (usually electrons) which flow into the atmosphere along the magnetic field lines. They typically occur near, but not quite at, magnetic poles because the field lines there connect to the largest regions of the magnetosphere.

Uranus. Uranus's magnetic poles, and therefore its auroras, are far from the geographic poles because of its large magnetic dipole tilt (60°) and offset ($0.3R_U$). Moreover, both auroras are on magnetic field lines that connect to the magnetospheric tail, so that the aurora-exciting particles (probably 10^4 eV electrons) streaming down the field lines into the atmosphere are still drifting toward Uranus. Because the plasma drift paths continue on past Uranus, on field lines where there is no aurora, it seems likely that the auroras are exhausting the available hot electrons before they can drift completely past Uranus.

The aurora is visible primarily at in the extreme ultraviolet at wavelengths between 90 and 110 nm, emitted by electronic transitions between low-lying states of molecular hydrogen. These bands are excited by the low-energy secondary electrons emitted when high-energy charged particles impact the atmosphere.

Neptune. Neptune's magnetic poles and auroras are also far from the geographic poles because of its large magnetic dipole tilt (47°) and offset ($0.55R_N$). The light from Neptune's aurora, like Uranus's, is extreme ultraviolet H_2 molecular band emission between 90 and 110 nm, stimulated by auroral secondary electrons. Some diffuse glow is also stimulated by electrons which are emitted by the day-side atmosphere in response to solar ultraviolet light and which follow the magnetic field lines around to impact the dark side.

Radio waves

There are a number of types of radio waves emitted by Uranus and Neptune with frequencies in the range 100–1000 kHz, both narrow and wide bandwidth and

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

emitted both in bursts and semicontinuously. Uranus's and Neptune's radio emissions are more similar to each other than to those of other planets. They can be observed from outside the magnetosphere, although, at the present orientation of Uranus, the strongest Uranian radio emissions are beamed away from the Earth

Several types are emitted from regions not far out of the atmosphere on the auroral field lines. In most cases they are generated by electron velocity distributions that are relaxing to equilibrium by means of collective instabilities. One of the ways to cause electron velocity distributions to depart from equilibrium, and so generate these waves, is to selectively remove part of the distribution by atmospheric absorption in an aurora, which is why these radio emissions are located there.

Most of the radio emissions are confined to a narrow range of directions, or beamed, and rotate with the planet. The rotation periods of both Neptune and Uranus were measured by timing the recurrent detection of these emissions in the weeks after each Voyager flyby.

Another radio emission emitted at Uranus, but only marginally at Neptune, is the radio noise produced by lightning discharges. The strength of these emissions suggests that lightning discharges are weaker at Uranus than at Saturn but considerably stronger than at Neptune and at Earth. At Neptune, however, whistler plasma waves (see below) originating from lightning were found instead. Therefore lightning does occur at Neptune, but the discharges must be much weaker than at Uranus.

Plasma waves

Plasma waves are collective disturbances in a plasma that are coupled to perturbations in the electric and magnetic fields and that move with respect to the plasma. They are, like the radio emissions, typically generated by departures of the plasma from thermal equilibrium. Unlike the radio waves, however, they do not propagate out of the plasma, and so cannot be observed from outside the magnetosphere.

The strongest of them, Whistler-mode noise, is caused by the depletion of magnetospheric electrons traveling along the magnetic field when they impact the atmosphere and create an aurora. This imbalance between the numbers of electrons with velocities parallel and perpendicular to the magnetic field is unstable, and the whistler-mode noise is generated by the motions of the electrons as they approach equilibrium. In the process, however, more electrons stream along the field and impact the atmosphere, perpetuating the process. Unsurprisingly, therefore, whistler-mode noise was observed at its greatest intensity at Uranus when Voyager was on field lines that were connected to the aurora.

Whistlers are plasma waves propagating in the same mode as whistler-mode noise (and vice versa) but are generated by a different process—lightning discharges. Whistlers are very short bursts of plasma wave noise that are spread out in frequency as they propagate along the magnetic field. In a radio receiver they sound like pure tones descending in frequency; hence the name. Whistlers emitted by lightning discharges were detected in Neptune's magnetosphere.

Current research

Mostly because of the lack of new data, Uranus and Neptune research has declined greatly in recent years. The HUBBLE SPACE TELESCOPE (or HST, a 2.4 m aperture orbiting telescope covering the wavelengths 115–2500 nm) and large-aperture ground-based telescopic infrared observations of the ionospheric species H_3^+ between 3890 and 4090 nm are the main sources of new data.

There are many questions for future research. How does Uranus's atmosphere smooth out such great seasonal extremes of solar heating? Why is Uranus's internal heat source so small compared with those of the other gas giants? Why is Uranus's stratosphere so much calmer and less mixed than other giant planet stratospheres? What is the high-altitude heat source that heats Neptune's and Uranus's upper atmospheres to such high temperatures? What is the pattern of motion of Uranus's and Neptune's magnetospheric plasma? What is the origin of bursty radio emissions? Why are Jupiter's, Uranus's and Neptune's radio emissions rotation controlled, while Earth's and Saturn's are solar wind controlled?

Uranus: Rings

The Uranian ring system comprise ten narrow rings, one diffuse ring and some tenuous material between the narrow rings. With a mixed nomenclature arising from historical tradition, the names of the ten narrow rings (in order of increasing distance from the planet) are 6, 5, 4, α, β, η, γ, δ, λ, ϵ; the name of the diffuse ring is 1986U1R. The innermost narrow ring lies about 16 000 km above the microbar pressure level in the Uranian atmosphere, and the entire ring system is about 10 000 km in radial extent. The distinctive feature of these rings is their narrowness, most having a radial width less than 12 km (table 1).

Although these rings can now be easily imaged from the Earth with modern detectors, they were first observed with the technique of *stellar occultations*. A stellar occultation occurs when starlight is blocked from an observer by an intervening body—in this case the Uranian rings. Observations are carried out with high-speed photometric equipment, ideally with several observing sites well spaced in the direction perpendicular to the motion of the ring shadows across the Earth. The recording of the starlight intensity as a function of time then provides a 'line scan' of the transmission of the ring material. With multiple observations of the same occultation by a network of telescopes, several points around each ring are recorded, and the ring orbits can be constructed. By repeatedly observing occultations over several years, one can learn the ring orbits to great accuracy. One advantage of the stellar occultation technique over ordinary imaging observations with Earth-based telescopes is that occultations achieve a spatial resolution (limited by *fresnel diffraction*) of just a few kilometers, rather than the much coarser resolution achievable with Earth-based telescopic observations.

The discovery of the Uranian rings with airborne and ground-based observations of a stellar occultation in 1977 ushered in the beginning of modern ring research. With only the broad, bright ring system of Saturn as an example (see SATURN: RINGS, no one had suspected the existence of dark, narrow rings. Any thought of narrow rings was quickly dismissed because collisions between ring particles would cause them to spread out into a broader ring over time. In order to explain the existence of narrow rings, theorists postulated the existence of small satellites near the rings, termed SHEPHERD MOONS, that would confine the particles through their gravitational interaction. This idea was borne out by VOYAGER's discovery of Prometheus and Pandora, two satellites that shepherd the narrow F ring of Saturn. Voyager also discovered Cordelia and Ophelia, the two shepherd satellites of the ε ring. However, pairs of shepherd satellites have not yet been identified for the other Uranian rings, so the mechanism(s) for maintaining narrow rings may not be completely identified.

In the two decades following their discovery, about 20 stellar occultations by the rings were observed, mostly in methane bands where the background light from Uranus is minimized. In 1986 the Voyager 2 spacecraft flew by the Uranian system and recorded several high-resolution images of the rings. In addition, the Voyager Photo-polarimeter Subsystem (PPS) and Ultraviolet Spectrometer (UVS) instruments observed stellar occultations by the rings, and occultations of the Voyager radio signal (from the Radio Science Subsystem, RSS) were observed from Earth. Due to the much closer vantage point of the spacecraft, the Voyager data have provided the highest spatial resolution observations of the rings that we have so far. In particular, the radio-occultation data at X-band has a resolution of 50 m, which can be compared with the 2 km resolution of ground-based stellar occultation data at visible wavelengths.

Table 1. Orbital properties† of Uranus's rings.

Ring	Semimajor axis (km)	Radial width (km)	Eccentricity	Inclination (degrees)
6	41 837.2	1.0–2.5	0.001 013	0.062
5	42 234.8	1–7	0.001 899	0.054
4	42 570.9	1–7	0.001 059	0.0323
α	44 718.5	4.5–10.5	0.000 761	0.0152
β	45 661.0	5.5–12	0.000 442	0.0051
η	47 175.9	55	∼0.004	∼0.0011
γ	47 626.9	1–8	0.109	∼0.002
δ	48 300.12	2–8	0.004	0.0011
λ	50 023.9	1.3–2.5	∼0.0	∼0.0
ε	51 149.3	20–96	0.007 936	∼0.0002

† Errors in these quantities are in the least significant digit, and values preceded by a tilde have an error comparable to the value. These results are from French *et al* (1991).

Several ring phenomena were first observed in the Uranian ring system. After the extreme narrowness of the rings, the most surprising of these is the elliptical and/or inclined orbits exhibited by some of the rings. Dynamical theories had predicted that rings would be limited to circular orbits in the equatorial plane of the planet. The eccentricities and inclinations are excited by the shepherd satellites, which can also produce an extremely sharp ring edge, if it is located at an exact orbital resonance with the satellite. Examples of sharp edges produced by resonances with the satellites Cordelia and Ophelia are the inner and outer edges of the ε ring, the outer edge of the δ ring and the inner edge of the γ ring.

Elliptical ring orbits exhibit PRECESSION, which is a slow change in the orientation of the ellipse. The precession of the ring orbits is caused by the oblate mass distribution within Uranus, and the rate of this motion gives us information about the interior structure of the planet. Here we can consider the rings as 'test particles' moving within Uranus' gravitational field. From their precessional motions, two of the gravitational harmonic coefficients have been precisely established ($J_2 = 3.3434 \times 10^{-3}$ and $J_4 = -2.89 \times 10^{-5}$). These allow the computation of the Uranian internal density distribution, which provides a constraint on allowable interior models for Uranus.

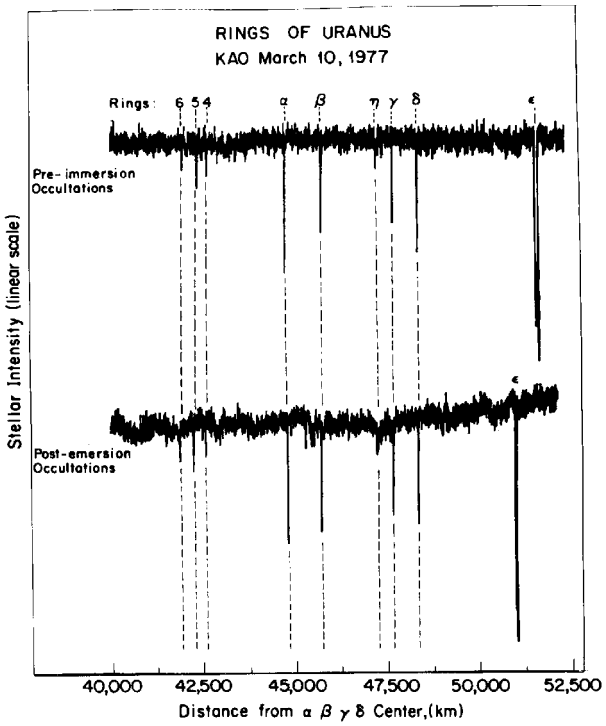

Figure 1. Discovery observations of the Uranian rings from the Kuiper Airborne Observatory. The intensity of starlight before and after Uranus occulted the star is plotted versus distance from the center of the planet. Nine dips were observed on each side, which occurred at the same radius, indicating that Uranus is encircled by a system of narrow rings. (After Elliot J L 1979 Stellar occultation studies of the solar system *Ann. Rev. Astron. Astrophys.* **17** 445–75. Reprinted, with permission, from the *Annual Reviews of Astronomy and Astrophysics* Volume 17, ©1979, by Annual Reviews www.AnnualReviews.org.)

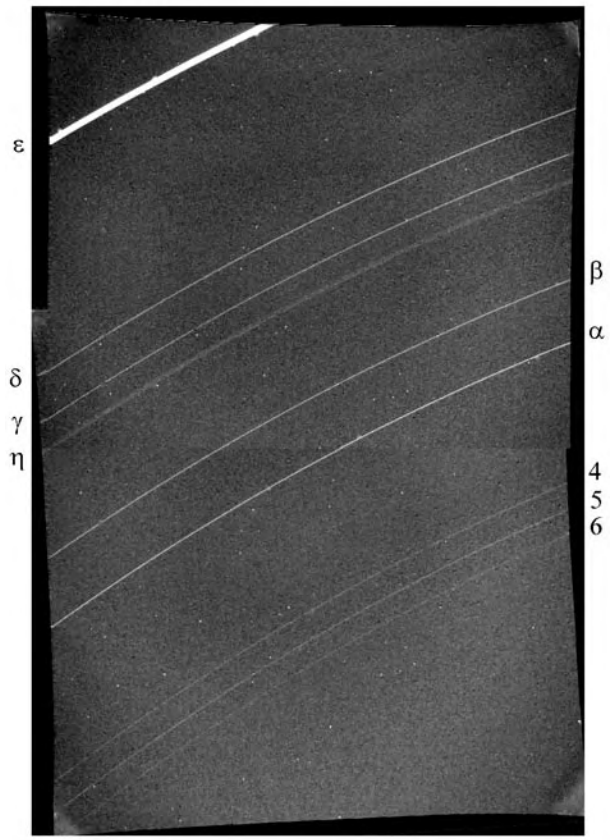

Figure 2. Voyager observations of the Uranian ring system. The three faint rings in the lower right are (in order of increasing radius) 6, 5 and 4; these are followed by α, β, η, γ, δ and ε. The λ ring is not visible. Ring ε contains the most material and is the brightest because it reflects the most sunlight. (Courtesy NASA/JPL/Caltech.)

The largest ring of the system (ε) has a minimum radial width of 20 km (at PERIAPSIS, its closest distance to Uranus) and a maximum 96 km (at APOAPSIS, its furthest distance). This width is a strict linear function of the ring radius, which implies that the precessions of the individual particle orbits are 'locked' at the same rate. If the precession rates were not all the same, then the orbits of the particles in the outer parts of the ring would precess more slowly than those for the particles closer to the planet, and the radial width of the ring would become uniform around the ring. The radial widths of rings α and β also vary linearly as with distance from the planet, but the variation is only 4.5 to 10.5 km for the α ring and 5.5 to 12 km for the β ring. One mechanism proposed for maintaining the locked precession of the particle orbits is the gravity of the ring particles themselves, but this has not been conclusively proven to be the case.

In discussing the structure of the Uranian rings, one property of interest is the *equivalent depth*, which is the *optical depth* (minus the natural logarithm of the ring transmission) integrated along the radial direction. Thus the equivalent depth measures the amount of material in the ring in a way that is independent of the angle at which the ring occults a star or other source of radiation. For most rings the equivalent depth is the same all around the ring, indicating a constant amount of material at each longitude of the ring orbit. Equivalent depth has the dimensions of length.

Rings 6, 5 and 4 have a structure similar to each other, being very narrow with equivalent depths of 0.8, 1.8 and 1.4 km. These rings have variable widths, but the widths do not correlate with orbital radius (as they do for the α, β and ε rings). The Voyager occultation data reveal significant internal structure. Rings α and β are more substantial, with equivalent depths of 6.0 km and 3.8 km respectively. These rings rarely exhibit the sharp edges characteristic of resonances with satellites (two sharp-edged profiles were observed for the α ring in the Voyager data). Rings γ and δ are concentrated, with equivalent depths of 6.6 km and 4.1 km. Each of these rings has an excited normal mode, with an amplitude of 5 km for the γ ring and 3 km for the δ ring. The δ ring may also have an internal density wave. The η ring is unique, with a sharp

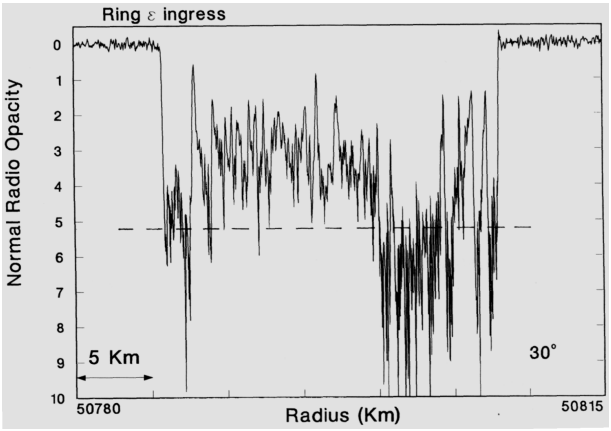

Figure 3. Occultation profile of the ε ring. This graph shows the normal radio opacity (optical depth) of the ring as a function of radius. Note the sharp inner and outer edges caused by orbital resonances with Cordelia and Ophelia and the detailed internal structure. Below the dashed line, the variations are mostly due to noise, rather than structure of the ring. (After Gresh D L, Marouf E A, Tyler G L, Rosen P A and Simpson R A 1989 Voyager radio occultation by Uranus' rings. I. Observational results *Icarus* **78** 131–68.)

inner feature (similar to rings 4, 5 and 6) and an adjacent broad, low-optical-depth component about 55 km in radial extent and with a sharp outer edge. Both components of the η ring follow circular orbits in the equatorial plane of Uranus. The λ ring is tenuous and clumpy, with an equivalent depth of only 0.1 km. Finally, the ε ring has very sharp inner and outer edges and an equivalent depth of 83.8 km. Its occultation profile has a 'W' shape, showing that its material becomes more concentrated at its edges (figure 3).

The rings are very flat—with a vertical thickness (perpendicular to the plane of their orbits) of only a few tens of meters. The ring particles themselves are dark, with ALBEDOS of a few per cent. Comparison of the occultation profiles of the rings at different wavelengths reveals that they contain very few particles smaller than centimeter sizes, with particle sizes tens of centimeters having been inferred in the ε ring. A Voyager image of the rings (in forward scattered sunlight) shows a small population of micron-sized dust particles in the ring system.

Compared with the other ring systems, Uranus' rings have less material than those of Saturn, but more than the ring systems of Jupiter and Neptune (see JUPITER: RINGS NEPTUNE: RINGS). All the Uranian rings lie inside the ROCHE LIMIT, which is the smallest radius for which a body can remain intact by its self-gravitational forces alone (without being pulled apart by the tidal forces from Uranus). For a satellite (such as Cordelia and Ophelia) to exist within this region, it must have sufficiently high density and/or tensile strength to prevent the tidal forces from Uranus breaking it up. In fact, each of the rings could have formed in this manner. Once formed, a ring is subject to erosion processes, such as radiation drag, meteoroid impact and drag from Uranus' exosphere. One can then estimate how long these processes could have been operating in the past, which sets limits on the age of the rings. Estimates along these lines suggest ring ages of a few $\times 10^6$ years—much less than the age of the solar system (4.5×10^9 yr).

Urey, Harold Clayton (1893–1981)

Chemist, born in Walkerton, Indiana, Nobel prizewinner for Chemistry in 1934 'for his discovery of heavy hydrogen'. It was at Columbia University that he isolated the isotope deuterium by distilling liquid hydrogen; in the Second World War, he directed the effort to separate uranium-235 from uranium-238 for the atomic bomb. At the University of Chicago, he worked on the origin of the elements, their abundance in stars, and the origin of the planets, including the chemical properties of the Earth. He invented a technique that used oxygen isotope-bearing minerals to date rocks and to measure paleohistoric water temperatures (see MILUTIN MILANKOVITCH). He analysed lunar rocks from the Apollo missions.

Ursa Major

(the Great Bear; abbrev. UMa, gen. Ursae Majoris; area 1280 sq. deg.) a northern constellation which lies between Draco and Leo Minor–Leo–Canes Venatici, and culminates at midnight in mid March. Its origin is uncertain, though it was known to the ancient Greeks, who identified it with two mythological figures—Callisto, a mortal who was turned into a bear after having fallen victim to Zeus's passion and whom he placed for safety in the sky, and Adrasteia, a Cretan nymph who raised the infant Zeus and whom in gratitude he placed among the stars. Its brightest stars were cataloged by Ptolemy (c. AD 100–175) in the *Almagest*.

The third-largest and probably the best known of the constellations, Ursa Major is easily recognized by the asterism of the Plough or Big Dipper, formed by seven of its brightest stars, α, β, γ, δ, ϵ, ζ and η, which since ancient times has been used for navigation, as a line drawn from β through α Ursa Majoris points to α Ursae Minoris (Polaris), a second-magnitude star that lies within 1° of the north celestial pole. The brightest stars of Ursa Major are ε Ursae Majoris (Alioth), magnitude 1.8, α Ursae Majoris (Dubhe), a very close binary with orange (K0) and pale yellow (F0) components, magnitudes 2.0 and 4.9 (combined magnitude 1.8), separation 0.7″, period 44.4 years, η Ursae Majoris (Alkaid or Benetnasch), magnitude 1.9, ζ Ursae Majoris (Mizar), a multiple system consisting of two white (A2 and A7) components, magnitudes 2.3 and 3.9, separation 14.4″, both of which have a fainter companion, which forms a wide optical double with 80 Ursae Majoris (Alcor), magnitude 4.0, separation 11.8′, β Ursae Majoris (Merak), magnitude 2.3, and γ Ursae Majoris, magnitude 2.4. There are 13 other stars of magnitude 4.0 or brighter. The five central stars of the Plough (β, γ, δ, ϵ and ζ Ursae Majoris) are part of the Ursa Major Moving Cluster, which is the closest star cluster to the Sun, its center being about 75 light-years distant.

Another interesting multiple star system is ξ Ursae Majoris (Alula Australis), which consists of two yellow (G0) components, magnitudes 4.3 and 4.8 (combined magnitude 3.8), separation 0.9–3.1″, period 59.8 years, the former of which has an unseen companion which revolves around it in 669 days, and the latter two unseen companions, one of which revolves around it in 3.98 days. The main components were the first binary system to have an orbit computed, by M Savary in 1828. Other interesting stars include Lalande 21185 (magnitude 7.5), which, at a distance of 8.3 light-years, is the fourth closest star to the Sun, and Groombridge 1830 (magnitude 6.4), which has the third largest proper motion of any star.

Other interesting objects include M81 (NGC 3031), a seventh-magnitude spiral galaxy, its near neighbor M82 (NGC 3034), an eighth-magnitude irregular, starburst galaxy which is thought to have experienced disruption following a near-collision with the much more massive M81 some 40 million years ago, and M101 (NGC 5457), an eighth-magnitude face-on spiral galaxy.

Ursa Minor

(the Little Bear; abbrev. UMi, gen. Ursae Minoris; area 256 sq. deg.) a northern circumpolar constellation which is surrounded on three sides by Draco and includes the north celestial pole. Its origin is uncertain, though it was known to the ancient Greeks, who identified it with Ida, a Cretan nymph who helped her sister, Adrasteia, raise the infant Zeus and whom in gratitude Zeus placed among the stars alongside Adrasteia (who is represented by the neighboring constellation of Ursa Major). Its brightest stars were cataloged by Ptolemy (*c*. AD 100–175) in the *Almagest*.

A small, rather inconspicuous constellation, Ursa Minor's only claim to fame is that its brightest star, α Ursae Minoris (Polaris or Alrucaba), lies within 1° of the north celestial pole. α Urase Minoris is actually a triple system with pale yellow (F7 and F3) components, the primary of which is a Cepheid variable (range 1.86–2.13 decreasing, period 3.97 days) and the secondary a star of magnitude 8.2, separation 18.4″, and a third, unseen component which revolves around the primary in 30.5 years. There are two other stars brighter than magnitude 4.0: β Ursae Majoris (Kochab), magnitude 2.1, and γ Ursae Majoris (Pherkad), magnitude 3.0, which together are known as the 'Guardians of the Pole'. The seven brightest stars of the constellation (β, γ, η, ζ, ε, δ and α) form an asterism similar to the Plough and are sometimes called the Little Dipper.

There are no bright star clusters, nebulae or galaxies in the constellation, the brightest being NGC 6217, an eleventh-magnitude spiral galaxy.

US Astronomy

As the 19th century ended, astronomy underwent a period of rapid growth in the United States, a growth that was fueled by both the expansion of the university system and private philanthropy and which also paralleled the growth in astrophysical research. For the first half of the 20th century, the US government took little interest in the funding of astronomical research, concentrating on those aspects of astronomy that were of greatest commercial and military interest: navigation and the determination of time.

Following World War II, the involvement of the US government in funding all branches of science grew and the National Science Foundation (NSF) established and built the national observatories. With the birth of space astronomy in the 1960s, the National Aeronautics and Space Administration (NASA) became a major force in astronomical research. Despite an increasing government presence, there remained a steady source of private and institutional funds contributing to the operations of astronomical facilities and to the support of research. Together with this growth in funding came steady growth in the number of practicing research astronomers in the US, a number which grew more than six-fold in the three decades from 1960 to 1990.

Funding sources

The dominant portion of US government funding for astronomy is provided through two agencies, NASA and the NSF. Other agencies supporting astronomical research include the Department of Defense, the Department of Energy and the National Oceanic and Atmospheric Administration.

NASA currently provides about 80% of the total federal funding, with most of the balance provided by the NSF. NASA funds astronomy through the Office of Space Science (OSS), which had a budget of 2.1 billion dollars in fiscal year (FY) 1999. This office funds the planning, construction, launch and operation of space-based astronomical observing facilities. It also provides funding for the archiving and analysis of data from space missions. Furthermore, the OSS operates some high-altitude observing facilities, which fly on balloons or airplanes.

The NSF division of astronomical sciences (AST) operates within the Mathematical and Physical Science directorate of the agency. Its budget for FY 1999 was 119 million dollars. The NSF operates several national observing facilities, directly funds astronomical researchers and provides some funding for educational purposes. The NSF also provides funding for the design, development and construction of national ground-based observational facilities. In FY 1999, 8 million dollars was allocated for the design and development phases of the ATACAMA LARGE MILLIMETER Array (ALMA, formerly known as the MMA or millimeter array), an international collaboration.

There are numerous sources of non-federal funding for astronomy. These include private organizations, private universities, state universities, state and local governments and private foundations. The amount of non-federal funding for astronomical research is difficult to determine owing to the broad array of sources. Universities typically provide a significant level of support through salaries for faculty members. Private universities such as the California Institute of Technology or Harvard University as well as public universities such as the University of California or the University of Texas also use institutional funds to support observatory operations. Among private organizations, the Carnegie Institution of Washington and the Lowell Endowment provide ongoing operating funds for specific observatories while other groups such as the Keck Foundation, the Sloan Foundation and the Ford Foundation have provided substantial funding for the construction of observatories or for specific research projects.

Facilities

To effectively study the diverse array of objects in the universe, observations must be made using all wavelengths of electromagnetic radiation. Some wavelengths of light are not able to penetrate the Earth's atmosphere. Some methods of observation require extensive instrumentation. Some direct physical data are gleaned from analysis of collected cosmic dust particles or meteoritic material. For these reasons, observations must take place both from the surface of the Earth and from space.

In the United States, observatories are funded by the Federal Government and through private sources. The NSF owns the facilities of and contracts for the operations of the National Observatories. These are as follows:

- the National Optical Astronomy Observatories, with observatories on KITT PEAK, Arizona, CERRO TOLOLO, Chile, and Sunspot, New Mexico;
- The NATIONAL RADIO ASTRONOMY OBSERVATORY, with observatories at Green Bank, West Virginia, Socorro, New Mexico, and Kitt Peak, Arizona;
- the National Astronomy and Ionosphere Center at ARECIBO, Puerto Rico.

In addition:

- The NSF provides operational support to a number of university radio astronomy facilities and the NSF Office of Polar Programs, which operates several astronomical facilities at the South Pole,
- the NSF is a member of an international optical telescope partnership named GEMINI, which has built two identical telescopes, one in the northern hemisphere and one in the southern hemisphere (the United States funds approximately 48% of the overall budget; see GEMINI OBSERVATORY).

The non-federally funded observatories are mainly supported through universities, consortia of universities

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

or private foundations. Many observatories operate with mixed sources of funding. For example, some observatories are constructed using university funds or with grants from private foundations and then rely on grants from the federal agencies to provide funds for development and construction of instruments and sometimes for operations.

In the last 10 yr, NASA has launched three of the four so-called 'Great Observatories'. These include the HUBBLE SPACE TELESCOPE, the CHANDRA X-RAY OBSERVATORY and the COMPTON GAMMA-RAY OBSERVATORY. The final Great Observatory, the SPACE INFRARED TELESCOPE FACILITY, is scheduled for launch in December 2001. These satellites have radically changed our view of the universe and provided unprecedented discoveries unattainable from the ground.

In addition to the Great Observatories series, NASA has a range of other missions from small to large. There are several major mission programs including Discovery, Explorer, Mars Exploration and New Millennium. Each mission has specific goals. Discovery missions explore objects within our solar system such as planets, moons and other small bodies. The Explorer program provides frequent flight opportunities at three separate funding levels for missions that support one of the four major themes of the Office of Space Science: university (less than $7.5 million), small (less than $71 million) and medium (less than $140 million). These themes are the Astronomical Search for Origins, Planetary Systems, The Sun–Earth Connection and the Structure and Evolution of the Universe.

NASA maintains 15 research centers across the United States, each of which fulfills various portions of NASA's overall mission. The centers most closely associated with astronomy missions include the GODDARD SPACE FLIGHT CENTER in Greenbelt, Maryland, the JET PROPULSION LABORATORY in Pasadena, California, and MARSHALL SPACE FLIGHT CENTER in Huntsville, Alabama.

NASA has led the way in archiving astronomical data. It has created numerous facilities such as the Hubble Data Archive, the Astronomical Data Center, the Planetary Node system and the Astrophysics Data System, which provide researchers access to archival data.

There has been a recent trend toward major projects, whether on the ground or in space, being undertaken through international collaborations because of the large costs and complexity of the projects. This trend is likely to continue into the near future.

Demographics and employment patterns

After a decade of rapid growth in the 1980s, the number of astronomers in the United States has grown more slowly but steadily in the 1990s. The median age of astronomical researchers has remained approximately the same, but the age distribution has widened somewhat with the number of astronomers in the age range from 35 to 50 decreasing from about 50% at the end of the 1980s to 40% at the end of the 1990s.

Toward the end of the 1990s there has been a leveling off and even a decrease in the number of students pursuing studies in physics and astronomy at the undergraduate and graduate levels in American universities. Almost all graduate students in astronomy or astrophysics have prepared themselves for graduate study by obtaining an undergraduate degree in either physics or astronomy. Among astronomy PhD recipients from US institutions in 1997, 19% were female and 27% were not US citizens (source: American Institute of Physics, *1997 Graduate Student Report*).

About six out of every ten astronomers in the United States are employed in academic institutions, colleges or universities, and slightly over half of these are in tenured or tenure-track positions. Most of the others are working in federal laboratories or research centers or for industrial contractors supporting these centers.

Research publications

The bulk of the research published in the United States appears in one of the four scholarly journals published by the astronomical societies. The AMERICAN ASTRONOMICAL SOCIETY (AAS) publishes *The Astrophysical Journal*, *The Astrophysical Journal Supplement Series* and *The Astronomical Journal*. The ASTRONOMICAL SOCIETY OF THE PACIFIC (ASP) publishes *The Publications of the Astronomical Society of the Pacific*. In addition, there is a section of *The Physical Review* (published by the American Physical Society) devoted to astrophysical research, and both *Icarus* (Academic Press) and *The Journal of Geophysical Research* (American Geophysical Union) publish research in planetary and space physics.

Annual Reviews, Inc., publishes a review volume, *The Annual Review of Astronomy and Astrophysics*. The Astronomical Society of the Pacific and the American Institute of Physics are the principal publishers of conference proceedings.

As technology has developed in recent years, there has been an increasing use of on-line preprint posting services for rapid dissemination of research results. The most popular of these is part of the arXiv e-print archive service hosted at the Los Alamos National Laboratory (http://xxx.lanl.gov/archive/astro-ph).

Amateur astronomers in the US

Astronomy appeals to nearly everyone. Since the sky is accessible to all, astronomy is blessed with a large and active amateur community. The US has a number of amateur organizations that serve many diverse purposes. These range from small local clubs that meet regularly to exchange advice on telescopes and host 'star parties' to large national organizations that coordinate research activities easily performed by amateurs. Some of the larger national organizations that include amateurs are listed in table 1.

Summary

Astronomy in the United States is ending a period that has lasted a few years more than a century and has seen the US emerge as a world leader in astronomical research. At the beginning of the 20th century, the US was leading observational astronomy into an era of increasingly powerful and sophisticated telescopes. The 40 in refractor had just been commissioned and the two powerful telescopes on MOUNT WILSON were in the near future. When these were put to work, our view of the universe changed completely. Edwin HUBBLE explored the extragalactic distance scale and we began to understand the expansion of the universe. These discoveries, in turn, spurred the construction of newer, more powerful telescopes such as the 200 in Hale telescope. Following the discovery of radio waves from cosmic sources, powerful instruments such as the Very Large Array were commissioned (see VERY LARGE ARRAY NATIONAL RADIO ASTRONOMY OBSERVATORY). The United States led the way in space beginning in the 1960s and opened new and previously unexplored regions of the electromagnetic spectrum for astronomical observations. A series of increasingly ambitious and complex spacecraft were built and operated, leading finally to NASA's Great Observatory Series, which reaches completion in the early years of the 21st century.

At the beginning of the 21st century, American astronomers have access to an unprecedented suite of instruments and techniques with which to observe the heavens. New technology has made possible the construction of telescopes of a size that was inconceivable a generation ago, and the Keck Telescopes, at 10 m each, have led the way in showing what can be achieved with such powerful instruments. The successors to the NASA instruments of the 1990s are being planned even while the current generation is at its peak of performance.

US Naval Observatory

The US Naval Observatory is the oldest astronomical observatory in the United States, and the oldest continuously operating scientific institution in the US government. Founded in 1830 as a Depot of Charts and Instruments for rating chronometers and maintaining navigational instruments, by 1844 it had become the first national observatory of the United States, analogous to the ROYAL OBSERVATORY IN GREENWICH, England. The observatory's headquarters are located in Washington, DC, including the historic 0.66 m refractor used to discover the two moons of Mars in 1877. The observatory's largest telescope, a 1.55 m astrometric reflector, is located at its station in Flagstaff, Arizona. The observatory's mission has always been to aid in the improvement of navigation as well as to conduct basic research in astronomy. Today, it provides the national time service for the United States, determines the precise positions and motions of celestial bodies, measures Earth rotation parameters including polar motion, and produces a variety of almanacs for use by astronomers, navigators and the general public.

Ussher, James (1581–1656)

The Archbishop of Armagh and Primate of All Ireland, Ussher was a churchman and a scholar. He correlated Middle Eastern and Mediterranean histories with Jewish genealogies of the Old Testament, and the resulting chronology was incorporated into the Authorized Version of the Bible of 1701. The chronology established the year of creation as 4004 BC. Lightfoot followed Ussher, improving on Ussher's accuracy by declaring that the Earth had been created at 6:00 a.m. on 26 October 4004 BC. The dates of other biblical events followed, for example, that Adam and Eve were driven from Paradise on Monday 10 November 4004 BC, and that the Ark landed on Mount Ararat on 5 May 1491 BC, 'on a Wednesday'. Ussher was a great scholar, if over-literal in his analysis of the Bible. He collected the earliest available manuscripts into his library, which formed the nucleus of the great library of Trinity College, Dublin.

Valles Marineris

A complex system of canyons on Mars, centered at 11.6 °S, 70.7 °W, stretching for a total of 4128 km in the east–west direction just south of the equator, and reaching depths of over 6 km. It is named after the Mariner probes which returned the first close-up images of the planet's surface, and is also referred to as Mariner Valley. Individual sections of the systems are termed chasmata. At its western end, where the system abuts the faulted area at the east of the Tharsis Bulge known as Noctis Labyrinthus, lie Tithonium Chasma and, to its south, Ius Chasma. To their east, the system expands into the three parallel canyons named, from north to south, Ophir Chasma, Candor Chasma and Melas Chasma. To the northwest lies the unconnected Hebes Chasma. The main system continues eastward with Coprates Chasma, and then opens out, via Capri Chasma to the north and Eos Chasma to the south, into the so-called chaotic terrain of the region known as Margaritifer Sinus.

Valles Marineris was created largely by faulting, but other forces have been at work. The deep branching valleys running into the southern edge of Ius Chasma suggest erosion by groundwater, while at the eastern end are teardrop-shaped islands suggestive of flowing water. Close up views of Coprates and the other central chasmata clearly reveal the presence of layered sediments, which could only have been deposited under water.

Valongo Observatory

The Valongo Observatory, part of the Federal University of Rio de Janeiro (UFRJ), sited in downtown Rio de Janeiro, Brazil, was founded in 1881. Its main activity is scientific research in the field of astronomy, carried out by its staff of twelve astronomers. The professors/researchers keep scientific collaboration programs with other institutions at both national and international levels. The main research areas are: fundamental astronomy, stellar astrophysics, interstellar medium, extragalactic astronomy and laboratory astrophysics. Funding comes chiefly from the Brazilian government agencies. The Valongo Observatory offers an undergraduate course in astronomy, attended by approximately 90 students. Its astronomical instruments include an original turn of the century Thomas Cook & Sons 30 cm refractor telescope, and a Zeiss reflector of 15 cm, for undergraduate teaching. As extracurricular activities, there is a visitation program offered to the general public, also serving secondary schools, which features telescopic observations and conferences given twice a month.

Van Allen, James (1914–)

Magnetospheric physicist, born in Mount Pleasant, Iowa, discovered the *Van Allen belts* that surround Earth. After war-time service, Van Allen used V-2 rockets on high-altitude experiments, specifying a replacement rocket, the Aerobee, when supplies of the V-2 ran out. During the International Geophysical Year (1957–8), the first American satellite, Explorer 1, carried a micrometeorite detector and a cosmic ray experiment designed by Van Allen. Data from Explorer 1 and Explorer 3 (launched 26 March 1958) revealed the existence of a doughnut-shaped region of charged particle radiation trapped by Earth's magnetic field. Later in 1958, Pioneer 3 led to the discovery of a second radiation belt.

van de Kamp, Peter (1901–95)

Astronomer, born in Kampen, Netherlands, became director of the Sproul Observatory and professor at Swarthmore College, PA. He worked on the astrometric measurement of proper motions of stars across the sky and discovered oscillations in their paths. He interpreted the deflections as due to the revolution of planetary systems around the stars. The oscillations have not been confirmed, and many astronomers think that they were instrumental effects caused by the telescopes and measurement techniques.

van Maanen, Adriaan (1884–1947)

Dutch astronomer, became a member of the Mount Wilson staff, and studied the rotation of spiral nebulae as a means to establish their distances. His detection of rotational motions was illusory and misleadingly suggested that they were relatively nearby. Through its proper motion and parallax, he discovered the white dwarf *van Maanen's star*.

Van Maanen's Star

This star in the constellation of Pisces, although faint, is of much importance as it is the nearest readily observable white dwarf—a class of star of considerable significance in studies of stellar evolution. The white dwarfs Sirius B and Procyon B are both closer, but their proximity to their much brighter companions makes them very difficult to study as individual stars.

Van Maanen's Star, also known by the catalog designation Wolf 28, is situated about 2° south of δ Piscium. It was discovered in 1917 by the Dutch-American astronomer Adriaan Van Maanen (1884–1946), from a comparison of plates exposed in 1914 and 1917, to have the large proper motion of 2.978″ per annum. Its spectrum is classified DG. With a parallax of 0.227″, it is only 14.4 light-years distant, yet its apparent magnitude is only 12.37, indicating that it has a very low intrinsic luminosity (its absolute magnitude is 14.1). It has been estimated that its diameter may be no more than 12 500 km, comparable to that of the Earth.

Van Vleck Observatory

The Van Vleck Observatory on the campus of Wesleyan University in Middletown, Connecticut, was built in the years 1914–16 upon the disassociation of the departments of mathematics and astronomy. It was named in memory of John Monroe Van Vleck, Professor of Natural Science at Wesleyan throughout much of the nineteenth century.

The primary instrument of the observatory is a visual refracting telescope of 0.5 m aperture and a focal length of 8.41 m. The crown and flint lenses were made by C A R Lundin of the Alvan Clark Co. and were installed on a Warner and Swasey mounting in 1992. The two lenses are separated by about 10 cm, allowing cleaning of all surfaces without disturbing them. Their alignment has thus not been altered, and this and other features make the refractor among the best for astronomical research. Since 1992, the telescope has been mainly used to determine trigonometric parallaxes and proper motions of many hundreds of faint nearby stars. In the last few decades the Van Vleck astrometric program has been one of the leaders in the use of parallaxes to respond to problems in stellar astrophysics.

In 1971, a 0.6 cm reflecting telescope was obtained from the estate of Richard Perkin, founder of the Perkin-Elmer Corp. Like the refractor, the on-campus site of this instrument has encouraged a monitoring program using photoelectric photometry and later CCD imaging capability, of properties of T Tauri variables and other young stars. The department of astronomy offers the BA and MA degrees, and research programs on both telescopes feature student participation at every level.

Variable Stars

Stars vary in many ways and for many reasons. Broad categories of variation include stars that pulsate, fluoresce, become veiled, are disturbed by companions, erupt, explode and even change their spots. Variations may be episodic, irregular, semi-regular or periodic. A separate wide class comprises the extrinsic variables such as eclipsing and tidally distorted binaries and gravitationally lensed stars, whose variations result from changing aspect, but here we survey the intrinsic variables.

The first recognized variable stars were novae and supernovae ('new' stars), with some very old records being astrophysically useful, chiefly because they fix the accurate date of a stellar explosion. Although the ancient accounts are obscure and fragmentary and do not recognize modern distinctions (such as nova versus supernova), the type of event may still be discernible. For example, a supernova can be visible for 6 months or even longer, whereas ordinary novae are prominent for a matter of weeks, so a nearby nova can mimic a distant supernova in brightness but is typically a much briefer event. Observations of exploding stars go back to several centuries BC with records of some objects from two or more places, and would go back further if not for library burnings. The records were kept by imperial astrologers in China (later in Japan and Korea) as the 'new' stars were considered important omens. Today's telescopic observations provide good statistics of novae, but useful statistics of the infrequent supernovae in our Galaxy rely on the old records. Events observed in other galaxies have demonstrated enormous differences in scale between supernovae and novae. Theory has shown those differences to be far greater than optical observations indicate, as supernovae release the vast bulk of their energy in invisible forms.

Except for novae, stars were regarded as constant until the mid to late 1600s, when the first non-eruptive variables were recognized. Most notable was the pulsating red giant *o* Ceti (Mira, the Wonderful) with its $\approx 330^d$ large-amplitude variations. An appearance and disappearance of Mira had been noticed by D Fabricius in 1596, but was taken to be a nova. The early histories of intrinsic and extrinsic variables are inextricably linked, as ideas about causes emerged only slowly over several centuries. Systematic recording replaced casual notes over the 1700s, with the improved records leading to further discoveries. Thus θ Serpentis was conclusively shown to be variable by E Pigott, confirming G Montanari's suspicions of a century earlier, and J Goodricke found periodic variation in δ Cephei, the prototype of *Cepheid variables*, and in the eclipsing binary β Lyrae. The improved records also led to some success in identifying variation mechanisms. Speculation of the late 1700s cycled among eclipses, moving and transient spots on rotating stars, and rotating distorted stars. All of these phenomena commonly occur, but early assignments to particular stars were usually wrong. Pulsation was advocated only much later. Algol was (correctly) said to eclipse by Pigott and Goodricke, but both later favored other ideas. Curiously, the eclipse hypothesis of Algol was cast into disrepute by discovery of variable stars that clearly were not eclipsing binaries, apparently from a wish to have all variables follow a single theory. Spots on rotating stars were very popular in the 1700s and 1800s, even for Mira, and have now returned for RS Canum Venaticorum, W Ursae Majoris, FK Comae and BY Draconis type binaries. As late as *c*. 1930, pulsating star velocity curves were fitted in terms of orbital parameters, even when there was little or no doubt about their pulsational origin. A common finding was that the orbit of a star's unseen (and non-existent) companion was actually inside the observed star. The orbit parameters would be printed anyway after a comment or two on the unphysical situation and the need to fit something. Although the reality of pulsation for Long Period Variables (LPVs) and Cepheids was not seriously disputed, there was much uncertainty in sorting true pulsators from a miscellany of competing phenomena. Most authors simply avoided explicit mention of pulsation while discussing effects that scarcely could be due to anything else, with an occasional remark that velocity variations might not really be due to line of sight motion of any kind. The popularity of pulsation was undeniable in the 1920s and 1930s, however, when up to 10% of *Astrophysical Journal* papers concerned Cepheids and related stars—remarkably high for one subject. Nearly all contributions were observational at that time, although major theoretical advances had already been made by A Ritter in the 1870s and 1880s and by A S Eddington in the 1920s. Full acceptance of spectroscopy's implications for the pulsation hypothesis took nearly a half century (*c*. 1890–1935), yet many kinds of pulsating stars were eventually recognized as a direct consequence of the radial velocity and temperature changes discovered spectroscopically. Not only the existence of radial motion, but its phasing compared with that of light curves, is a crucial discriminant among models.

Realization that large numbers of variable stars exist was slow to develop until the breakthrough of photography. Only ≈10 non-exploding variables were known in the early 1800s, but the permanent records in photographic plates quickly extended the list into the hundreds between 1850 and 1900. Systematic photographic surveys in the 1900s at Harvard, Bamberg, Leiden and other observatories raised catalog listings into the tens of thousands. Recent automated gravitational lens surveys with electronic detectors have produced light curves of thousands of variables as a by-product of the surveys' primary objective, thereby substantially

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

increasing the discovery rate. The *General Catalog of Variable Stars* ('GCVS', Kholopov 1984) is a four-volume listing of coordinates, types and other information on 28 211 variables of all kinds, nearly 70% being intrinsic variables. A companion catalog of *New Suspected Variables* ('NSV', Kholopov 1982) contains 14 811 stars of uncertain status.

A reasonably complete list of variable star types with minimal descriptions would exceed available space, but the GCVS devotes five pages to descriptions. It recognizes 88 types of intrinsic variables, including 34 pulsating, 7 rotating, 10 x-ray, 22 eruptive and 15 cataclysmic types (cataclysmic and other eruptive variables are kept distinct). A standard naming convention allows immediate recognition of a star as variable, although some bright variables have only their Bayer names. To begin the sequence, a single capital letter is assigned alphabetically in order of discovery from R to Z, then double letters RR, RS, …, RZ, then double letters AA, AB, … to AZ, then BB, BC, … to BZ, and ultimately to ZZ, followed by the constellation name (e.g. T CrB; ZZ Cet). Letter J is not used. Designations of the form V335 Cygni, V336 Cygni, etc. follow the 334 names of the letter system.

There is great interest in variable stars among amateur astronomers, whose observations are indispensible for professionals. Not only visual brightness estimates but phototube and charge-coupled device (CCD) measures are now made available in large quantities through bulletins, journals and especially the Internet. Variable star organizations include the American Association of Variable Star Observers (AAVSO), the Association Française des Observateurs d'Etoiles Variables (AFOEV), the British Astronomical Association Variable Star Section (BAAVSS), Bundesdeutsche Arbeitsgemeinschaft für Veränderliche Sterne (BAV), the Center for Backyard Astrophysics (CBA), the Hungarian Astronomical Association, International Amateur-Professional Photoelectric Photometry (IAPPP), the Variable Star Group of the Astronomical Society of Southern Australia, Variable Star Network (VSNET), and the Variable Star Section of the Royal Astronomical Society of New Zealand. Information on all these organizations can be found via the Internet. Their imprints on professional astronomy date at least as far back as the 1920s—for example in Joy's use of an AAVSO Mira light curve in the 1926 *Astrophysical Journal*. The role of such organizations is rapidly expanding today. The central professional organization is Commission 27 of the International Astronomical Union.

LPVs and Cepheid variables were not only discovered early but still dominate our catalogs. LPVs are pulsating red giant stars of great luminosity and are thereby rather easy to discover. The name *Mira type* is reserved for the LPVs of larger light amplitudes, although there probably is continuity in the overall class, including Galactic distribution, space velocity and composition as well as light variation. There may also be continuity with 'non-variable' red giants, which probably have some variation. Spectra of LPVs and especially Miras show prominent emission lines that are clearly due to pulsation, as non-variable red giants lack emission lines but otherwise have similar spectra. More specifically, pulsation amplitude correlates with emission line strength. Miras vary by up to 9^m in blue light (a factor of ≈4000), but the enormous optical variations are caused by emission being ultra temperature-sensitive, with the optical band lying far to the short-wavelength side of the spectral energy peak. Bolometric amplitudes are similar to those of Cepheids. A problem for spectroscopy, especially prior to modern efficient spectrographs and large telescope apertures, was the faintness of Miras near minimum light. Observations must cover full cycles if much is to be learned about pulsation, and it was only in 1926 that A Joy produced the first complete velocity curve of Mira. The classical Cepheids are highly luminous F and G type pulsating giants and supergiants that vary periodically up to roughly a magnitude. Periods range from a few days to over 100 days. Rather early it was realized that the important relation between period and mean density

$$P\sqrt{\rho} = \text{constant}$$

applies to Cepheids and several other prominent categories of pulsating stars. The relation exists because a star's dynamical timescale depends on its size and mass, with some dependence on internal structure (thus a different constant for each category). Stars with given HR diagram coordinates have the same size, but not necessarily the same mass and structure, so pulsation periods provide a link to structure and thereby to understanding evolution. The W Virginis stars, members of a very old Galactic population, pulsate with their own $P\rho^{1/2}$ relation and are understood to be in a later evolutionary stage than classical Cepheids, having lost much of their original envelopes. Thus pulsation is an important evolutionary diagnostic that can even help trace Galactic origins.

In addition to the essentially periodic and roughly periodic classes of pulsating stars, there are giants and supergiants of spectral classes F to M that pulsate irregularly or semi-regularly. Curiously they lie mainly *between* the more regular Cepheids and LPVs in the HR diagram. The less regular and typically redder of these are known as RV Tauri stars, while the somewhat more regular ones are simply called yellow semi-regular variables. Periods, in so far as they can be quantified at all, range from tens to thousands of days, and amplitudes can be up to about four magnitudes. These stars may be interesting in terms of chaos theory, as some show

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

alternating cycles of larger and smaller amplitude that hint of the period doubling seen in the approach to chaos.

Brightness measurement

We have astrophysically useful records of the brightness variations of the supernovae of 1572 and 1604, as observed by T Brahe and others and by J Kepler respectively, despite lack of light detection equipment and even of telescopes 400 years ago. Their usefulness illustrates two points about astronomical brightness measurement. First, although precision requirements are stringent for small variations, they can be relaxed for large variations. Second, in no case can we allow the scale to be wrong, unless mere detection of variability is the only objective. One might expect eye estimates to be quantitatively useless, but Brahe's and Kepler's light curves demonstrate otherwise. The situation has been saved by the 'secret' advantage of the photometric astronomer—the remarkable long-term constancy of normal stars. Brahe and Kepler recorded their supernovas' magnitudes relative to known stars that, as far as we know, are essentially unchanged in brightness. Modern photoelectric observations of the reference stars have accordingly placed the supernova estimates on an objective scale. Of course the old estimates are subjective, but the largest overall errors are limited by the magnitude spacings of reference stars. An estimation method involving magnitude steps, introduced by F Argelander about 1840, further diminished maximum errors.

The existence of natural constant brightness standards largely accounts for the accuracy of astronomical photometry, which is typically better than that of laboratory photometry despite the disadvantage of observing through Earth's irregular atmosphere. Astronomers also have an advantage in the temperatures of reference sources, as very hot laboratory standards would vaporize their surroundings, while hot stars have no surroundings to vaporize. Difficulties due to daylight and weather as well as complete blockage of spectral regions are best dealt with by observing from space, although many less severe problems have been minimized through a variety of clever techniques.

The history of star brightness measurement can roughly be divided into an early era of qualitative notes (*c*. 1600 to *c*. 1800), a middle era of quantitative but inaccurate estimation by eye or photography (beginning *c*. 1800 and still somewhat active), and a recent era of accurate quantitative measurement with various electronic detectors (beginning *c*. 1910). Even the early qualitative work was a major improvement on the unplanned occasional notices of preceding times. It made possible the discovery of *periodic* variation and, coupled with long baselines in time, even accurate periods. Thus Goodricke estimated Algol's period in 1784 with an uncertainty of less than a minute out of 2.87 days. Entering the middle era, note that the eye can reliably judge brightness equality between two stars, a point well appreciated and exploited by F W Herschel, J Herschel, Argelander, J Hartmann and K Schwarzschild, but eye estimates of inequality are notoriously subjective. The better visual work accordingly employed a variety of now obsolete ways to reduce the apparent brightness of one star by a known factor so as to equal that of another. Techniques, sometimes applied also to photographic observing, included partial aperture blocking with twin telescopes, extra-focal imaging, tapered neutral filters (wedges), and crossed polarizers. Photographic magnitudes were extracted from diameters of focused images or blackening of unfocused images. The modern definition of astronomical magnitudes, relating magnitude (m) differences to light (l) ratios, $m_1 - m_2 = -2.5 \log (l_1/l_2)$, was suggested in 1850 by N Pogson. Simple as it may seem, Pogson's contribution was crucially important, as the quantitative meaning of magnitudes had previously been vague. The new accuracy and increased time lines allowed period *changes* to be measured, with S Newcomb's text of 1884, *Astronomy*, already mentioning period changes for Algol, Mira and β Lyrae. The above-mentioned accuracy tricks work only within small fields, so measurement of actual magnitudes, as opposed to 'local' magnitude differences, received a large boost with the arrival of photoelectric detectors. Invention of the photomultiplier tube in the 1940s especially helped to surmount atmospheric attenuation problems via all-sky photometry, and also greatly improved accuracy of magnitude changes for variable stars. Development of modern standard magnitude systems began when photomultipliers came into widespread use. Examples include the *U*, *B*, *V*, *R*, *I*, *J*, *K*, *L* wide-band systems and the *uvby* medium-band systems. A *standard star* has accurately known constant magnitude in one or more standard systems (e.g. γ Oph has $V = 3^m.72$, $B = 3^m.76$), while a *comparison star* has (presumably) constant but not necessarily known magnitude. CCD detectors similar to those in video cameras are now replacing photomultipliers because of their ability to measure many sources simultaneously and thus provide for accurate differential photometry. New practical problems have arisen out of the enormous quantities of data coming from CCD photometry. Advanced computer technology is being applied to storage and distribution problems, in some cases with data collection directly from the detecting equipment. Automatic telescope operation is becoming ever more widespread in many spectral regions, not only in discovery modes (as in extra-Galactic supernova searches) and quick follow-up on γ and x-ray transients, but also in routine observation of known variables. The acronym APT, for Automatic Photometric Telescope, implies remotely operated, programmable instruments that are primarily used for variable star research.

Astrophysical importance of variable stars

The scientific value of variable stars can be seen in two issues—why they vary (theory) and what their variations allow us to measure (observation). The theoretical point connects physical makeup with behavior, while the observational one concerns properties such as size, distance and internal structure that are measurable or estimable because of variation.

Most astronomical distance estimates are based on the *standard candle* method, a comparison of apparent and intrinsic brightness. The extra-Galactic distance scale is an important application, and distances to multiple stars and clusters within our Galaxy also are found from embedded standard candles. The method applies to any stellar group that contains a standard candle and whose diameter is small compared with its distance. Good standard candles are *consistent* (small luminosity range among individuals), *highly luminous* (for observation at great distance) and reliably *recognizable*. Variable stars naturally satisfy the recognition requirement, while some types satisfy the other requirements reasonably well and in some cases quite well. Cepheids, being giants and supergiants, can be observed in distant galaxies. Individual Cepheids differ in luminosity by factors up to about 100 and so might seem not to satisfy the consistency requirement, but H Leavitt discovered (*c*. 1905) that Cepheid luminosities are closely related to their directly measurable periods of brightness variation. After calibration, the *period–luminosity (P–L) relation* allows Cepheids to be used as standard candles, although essentially correct calibration required another half-century and is still being refined. However, even faulty early calibrations established distances to galaxies that were correct to an order of magnitude and thereby helped elucidate the nature of the 'spiral nebulae' and the scale of the Universe. Early applications were E Hertzsprung's distance estimate for the Small Magellanic Cloud and H Shapley's work on the extra-Galactic distance scale, following E Hubble's discovery of Cepheids in several galaxies. The distinction between Galactic and extra-Galactic objects was well established by 1925, five years after the famous Shapley–Curtis debates, when Hubble found 11 Cepheids in galaxy NGC 6822 and derived a distance. The Hubble Space Telescope and large ground-based telescopes have recently produced important increases in the Cepheid distance limit. Several kinds of exploding stars have very high luminosity, but Type Ia supernovae are best for recognition and consistency, in addition to being especially luminous. However, even the far less luminous and far less consistent ordinary novae have been used as distance indicators.

The large-amplitude pulsations of Cepheids and related variables can be exploited to measure radii rather directly. Luminosities then follow from combination of the radii with effective temperature ($T_{\rm eff}$) estimates, so as to provide standard candles. Observed variation is due to separable changes in surface brightness and size. 'Wesselink radii' (after A Wesselink) require three kinds of accurate observations—a radial velocity curve, a light curve and a color index curve (briefly 'color curve'—formed by differencing light curves (in magnitudes) for two effective wavelengths). Color curves of Cepheids resemble their light curves at first glance, having smaller amplitudes and subtly different shapes. Points with given color occur at paired times that are close together near a color maximum or minimum and well separated at intermediate color. The basic idea is that color index is a reliable indicator of $T_{\rm eff}$ and therefore of surface brightness. However, a quantitative relation to predict surface brightness from color is not needed—just the reasonable assumption that when the star returns to a given color it also returns to the 'original' surface brightness. Any change in observable light, l, between those two times is due to changed surface area, so the ratio of radii at the two times is

$$\frac{R_2}{R_1} = \sqrt{\frac{l_2}{l_1}}.$$

The difference of radii follows from an integration between the corresponding points on the radial velocity curve,

$$R_2 - R_1 = \int_{t_1}^{t_2} v_r \, \mathrm{d}t.$$

Now having both ratio and difference, we find the individual radii at the two times. Repeating the procedure for many time pairs, we find the run of R with time. The fundamental assumption that surface brightness is a unique function of color for a given star may not be quite true, but is close enough for useful applications. With actual radii in kilometers and with model stellar atmosphere predictions of surface emission per unit area, a final step computes luminosities. The method is one of the few direct means to find accurate radii of giant stars and to calibrate P–L relations.

Another natural situation to exploit is the existence of variable stars in binaries and multiple star systems, where the variable star and binary star characteristics should be compatible if our evolutionary understanding is correct. For example, the age of a variable should agree with that of its companion(s), and its absolute dimensions and distance may be derivable from observations of the binary or multiple system. Examples include δ Scuti (see below) type members in Y Camelopardalis and AB Cassiopeia, a Cepheid in V350 Sagittarii, and a β Cephei star in 16 Lacertae. It is important to discover more such systems.

There are few probes of stellar interiors so it is important to have a *wide variety* of checks on global and

surface properties, and the measures provided by pulsation and other forms of variation are welcome. For example, Cepheid masses can be inferred from both evolutionary and pulsational models, so the comparison either provides a check or sounds an alarm. Light curve and velocity curve details also can be predicted from pulsation models. The help comes where needed, as pulsational instabilities occur primarily in highly evolved stars where structure is complicated and theories are uncertain. Not only stellar structure theories but also equations of state, opacities, and energy generation rates ('laboratory physics' in principle but not in practice) are thereby subject to scrutiny.

On a wide front, galactic evolution is largely understood in terms of population types. For example the *RR Lyrae* type pulsating stars found in globular clusters and spheroidally distributed Galactic populations are not just short-period Cepheids, but have quite different Galactic distribution, motions, history and structure. Insight into RR Lyraes and Cepheids can apply to their non-variable neighbors in the HR diagram. On the observational side of galaxies, certain variable stars can be recognized at large distances and thus serve as population indicators.

Pulsation studies have now broadened into the rapidly developing field of asteroseismology, in which new observing methods and theoretical work on stellar oscillations extract structural information from multiple-frequency small amplitude variations in light and velocity. Applications to the Sun (helioseismology) are particularly successful because the Sun is spatially resolved and because it has a rich spectrum of oscillations. The directly tapped energy of solar oscillations is that of convective motions in the outer envelope that generate sound waves. Certain other kinds of stars, such as Ap, δ *Scuti* (see below) and especially some white dwarf stars, show intricate oscillations that are clues to their evolutionary states. World-wide observing networks such as the Whole Earth Telescope (WET) allow the long, nearly continuous, coverage needed to separate closely spaced frequencies.

Explosion mechanisms

Nova theories of the early to mid 1900s involved rapid contraction to the white dwarf state or dynamical resonances combined with nuclear reactions. Those theories now seem inapplicable to known kinds of stellar explosions. A modern schematic model that covers many particular categories includes a donor star to provide a supply of gas and an accreting star on which eruptions occur. The flow may be a stream from overspilling a critical lobe or it may be a wind, and the eruptions may be powered by thermonuclear or gravitational energy. Ordinarily the donor is non-degenerate while the accretor is some kind of compact degenerate object, and most commonly a white dwarf star. Neutron star accretors are much rarer, and main sequence donors greatly outnumber evolved donors, but a wide variety of combinations occur. An especially abundant class is that of the *cataclysmic variables* (CVs) where the compact object is a white dwarf, although the white dwarf often cannot be detected directly. In most CVs the companion is a low-mass main sequence star, the orbit period is well under a day, and the entire binary is similar in size to the Sun, and smaller in many cases. CVs are typically old objects as shown by their distribution in the Galaxy, which is in a thicker disk than ordinary Population I stars.

A major clue into mechanisms and evolution was the inferred presence, via radial velocities and light curves, of white dwarfs in post novae, recurrent novae and nova-like variables in the 1950s to 1960s. Although thermonuclear models had been proposed earlier, ideas for explosions soon focused on accretion-driven surface hydrogen-burning runaways on white dwarfs. CV component masses are difficult to estimate, but the white dwarfs are typically much more massive than their non-degenerate companions. Relatively massive donors should be subject to unstable mass transfer that would radically change the configuration (flow from high to low mass or between comparable mass stars favors instability). Evolved donors (giants and subgiants) have the same problem—for structural reasons they tend to expand, overflow their lobes and transfer gas unstably on a large scale. So the lack of evolved and of relatively massive donor stars is commonly explained by their self-destructive tendencies. However, a CV needs some level of slow mass transfer to fuel its eruptions. A suitable level can be maintained by orbit shrinkage due to magnetic wind braking or gravitational radiation.

Classical novae brighten by 9^m or more over a few days and then decline irregularly over weeks for fast novae or months for slow novae. Symbiotic novae (see below) are much slower (duration ≈ decades) than the slowest classical nova and are much wider binaries than the ordinary CVs. The mass donor is typically a giant. For classical novae, more or less standard spectral developments occur, with emission and absorption line episodes and ejecta velocities of the order of 10^3 km s^{-1}, but with a large velocity range among examples. Interpretation is difficult, as the state of the gas is hard to compute and the dynamical situation is intricate, with multiple velocity systems seen at most times. Classical novae have had only one known outburst, but that circumstance is attributed to the short history of observational astronomy. Thus there are also *nova-like variables* that are probably the same as classical novae but have not exploded in (astronomical) historical times. Observations of post-novae find the underlying binaries not markedly changed by their outbursts.

Recurrent novae explode like classical novae but the eruptions are frequent, typically decades apart. Current thinking favors accretors that are close to the white dwarf

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

mass limit, such that only small accretion build-up is needed to start a thermonuclear runaway. Chemical abundances in the ejecta do suggest advanced nuclear processing, as expected for remnants of stellar cores near the edge of collapse.

A computation of simple energetics shows that gravitational energy alone can power a large outburst from a white dwarf for a plausible sudden accretion episode. Objects identified with that mechanism are the *dwarf novae*—CVs that have cyclic outbursts with high repetition rates. Brightenings of up to about five magnitudes are separated by typical intervals of weeks to months and complicated shorter-term behavior includes fast flickering. Ideas to account for the episodes include sudden release of matter from a circumstellar disk (disk instability) and variable supply from the donor star (source instability). Examples are SS Cygni, U Geminorum, Z Camelopardalis and SU Ursae Majoris, each a prototype in a finer classification. Thermonuclear energy may play some role in dwarf novae. Ideas about evolutionary relationships among the several kinds of CVs are under continual revision.

Impressive as they are, CV explosions are small firecrackers compared with supernovae. In contrast to CVs, where the basic configuration remains after an explosion, a supernova event involves the entire star. Supernova mechanisms include thermonuclear incineration of a massive white dwarf star (in a binary) and collapse of an old, dense stellar core to nuclear degeneracy. Other types that are probably much less common have been proposed. The energy release in burning a white dwarf star can be estimated by multiplying a white dwarf mass ($\approx 3 \times 10^{33}$ g) by c^2 and by an efficiency factor ($\approx 10^{-3}$ for helium burning and beyond) to arrive at an energy between 10^{51} and 10^{52} erg, about a million times that of a typical nova. The minimum energy of a core collapse supernova is even much larger and follows from energy conservation in formation of a neutron star, whose gravitational binding energy, E_g, is of order -10^{53} erg. Obviously a positive energy that at least matches E_g must appear in the radiative and material ejecta. The visible radiation amounts to only $\approx 10^{48}$ to 10^{49} erg, and thus is a tiny fraction of the energy budget. Theoretical simulations indicate that nearly all of the energy is carried by neutrinos. The detection of about two dozen neutrinos from supernova 1987a in the Large Magellanic Cloud was a great triumph of supernova theory, as the number observed was the number predicted for a core collapse, within the uncertainties.

Pulsation

Pulsating stars undergo true pulsations (oscillations in size or shape). The pulsations are of the envelope, as the core is static and not directly involved. One could imagine the high-temperature sensitivity of nuclear reactions leading to core pulsations (the ϵ mechanism), but theory predicts that core pulsations will be quickly damped, except for supermassive stars. There are no candidates for core pulsation among the recognized variable stars, except perhaps the bizarre object η Carinae (see below) which may be a supermassive pulsating star. Pulsations grow when there is net conversion of thermal to mechanical energy, so the star is a heat engine. There are zones that *drive* pulsation (net [thermal $\Rightarrow$ mechanical]) and others that *damp* pulsation (net [mechanical $\Rightarrow$ thermal]). Elementary thermodynamics requires net heat injection in the compression stage if heat is to be converted to work so that the engine runs. However, direct injection of heat around maximum compression (as in an ordinary engine) is not the only way. Eddington realized in the 1920s that favorable circumstances could occur if a star is relatively heat-tight when compressed. Rather than thermal energy being inserted, its escape is prevented. This is the famous Eddington *valve* mechanism—a generic means to achieve net driving that covers all specific ways to implement heat-tightness upon compression. Two specific ways are the κ and γ mechanisms. The κ mechanism traps thermal energy by making material in driving zones more opaque upon compression (κ is the usual symbol for opacity). Kramers' Law, $\kappa = \kappa_0 \rho / T^{3.5}$, provides roughly correct opacity for given density (ρ) and temperature (T). With ρ and T entered from accurate stellar structure models, it predicts that stellar material becomes *less* opaque upon compression, and indeed most stars do not pulsate. However, actual opacity depends in a complicated way on thermodynamic variables and, although it decreases with compression in most parts of most stars, it *increases* with compression in the driving zones of Cepheids and some other pulsating stars. The γ mechanism operates by increasing the surface density of absorbing particles upon compression. Imagine a thin pulsating shell of gas at its maximum and minimum radii. The number of contained particles is the same whether the shell is large or small but the number per unit area is greatest when the shell is small. Therefore the shell more effectively blocks radiation, or is more heat-tight, when compressed. The γ mechanism always contributes to driving for obvious geometrical reasons, while the κ mechanism can produce either driving or damping.

Driving will be weak if the main driving zones are too close to the surface (high) or too deep inside the star (low), and net damping will arrest pulsation. In the high case, the problem is insufficient density in the driving zones so that too little matter contributes to driving. In the low case, the driving zones lie in the nearly adiabatic interior where, although there is plenty of mass, each gram makes only a small contribution. Because driving is associated with ionization zones of the abundant elements H and He, net driving zones will be high in relatively hot (blue) stars and low in relatively cool (red)

stars. Thus we have a roughly vertical *instability strip* in the HR diagram where Cepheids are found. However, its red and blue borders are not well defined and many non-pulsating stars lie within the strip. The instability strip extends down to and below the main sequence and includes the little-evolved or mildly evolved δ Scuti and related variables with their typical periods of hours. It then continues to the region of the pulsating white dwarfs (ZZ Ceti stars).

Several major distinctions characterize stellar pulsations. To begin, there are radial pulsations that preserve a star's figure (shape) but change its volume, and non-radial pulsations that preserve volume but vary the figure. An example of radial pulsation could be the expansion and contraction of a balloon under cyclically changing external pressure. A small-amplitude example of the non-radial case is provided by the tidal distortions of the Earth and its oceans. A large-amplitude example would be the oscillations of a disturbed water globule. A more formal description of the contrasting behavior is in terms of a vector field. In radial pulsation, the displacement vectors of local matter elements pass back and forth through zero length but maintain fixed alignments along local radii. Non-radial pulsation is more complicated, with the vectors cyclically changing both length and direction. Of course, real pulsations need not be purely radial or non-radial but can involve both volume and figure changes. However, many realistic situations approximate these idealized types.

Another distinction involves fundamental and overtone pulsation. The situation is conceptually the same as for a flexible string with one fixed and one free end, where the free end is the analog of a pulsating star's surface. The string can have a fundamental oscillation, with a node only at the fixed end, and also overtone oscillations with 1, 2, 3,…, *n* additional nodes. At a given instant, adjacent inter-node regions have opposite motions (up versus down), and of course there is no motion at the nodes. Similarly a pulsating star can have fundamental and overtone pulsations, with extra nodes for the overtones. For a uniform string the nodes will be equally spaced, but a star has inwardly increasing density, with the consequence that node spacings are not even approximately equal and must be computed. Fundamental and overtone pulsations can coexist and, accordingly, some unusual stars show beat phenomena.

Still another distinction is among pulsation *modes*, i.e. possible ways to pulsate. The large amplitude radial pulsations of Cepheid and RR Lyr type variables are in *pressure* modes (p-modes), so called because they involve large local pressure variations. Both radial and non-radial p-mode pulsations can occur. *Gravity* modes (g-modes) involve global oscillations about a hydrostatic level surface and are necessarily non-radial. They have much smaller pressure variations than do p-modes. Of course, energy can feed from one mode to another and between fundamental and overtones.

No one kind of pulsation analysis serves all purposes. As in other areas, success in computing detailed behavior does not guarantee understanding. The general phenomenon is highly nonlinear and one might expect maximum insight to follow from all-encompassing computations, but much insight has been gained from linear analyses in which only infinitesimal pulsations are studied. N Baker realized that outcome by restricting attention to a single mass shell—the One Zone model. However, pulsating stars are complicated structures with many (thermally and mechanically) coupled zones, so quantitative predictions of periods need complete models. To view the problem the opposite way, a full nonlinear computation should settle into a correct period, but will not identify all possible periods found from linear theory. Although linear analysis leads to insight on several fronts, it deals only with infinitesimal pulsations and therefore cannot produce complete models for comparison with observations. Possible pulsation modes and overtones are identified through linear analysis, with detailed behavior at finite amplitude examined via nonlinear analysis, including possible interactions of fundamental and overtones. Similarly, growth and decay rates of small-amplitude pulsations can be investigated via linear analysis, but rates for large pulsations and final saturation amplitudes are matters for nonlinear analysis. Of course, specific light and velocity curve features can be modeled only with full nonlinear computations.

A wealth of observed phenomena in pulsating stars remain only partly understood or have only recently been understood, including light versus velocity phase lags that are characteristic of a given class, unusual surface abundances, changing velocity amplitudes and multiple periodicity. Magnetic fields, fast rotation and binary companions are clearly present in some cases, but their roles in pulsation are not usually obvious. Specific driving mechanisms may not be clear. An active testing ground for pulsation theory is provided by the *β Cephei stars*, a class sometimes called the β Canis Majoris stars, although current usage seems to have settled on the name β Cephei. These stars have remarkably short pulsation periods of order $0.^d2$, with about half being doubly periodic and thereby showing beat behavior in light and velocity. Many RR Lyr and δ Sct stars also are doubly periodic, but the two periods of a β Cep star can differ by as little as 1%. The prototype β Cephei (not itself doubly periodic) is strongly magnetic and at least a triple system, with weak B-emission (Be) characteristics. A phenomenon that must occur but is difficult to model is that of dynamical tides in eccentric and/or asynchronous binaries, which can be regarded as forced non-radial pulsations. Like ocean waves, such tides are largely stochastic so that prediction is mainly limited to

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

statistical behavior. Several supergiants with neutron star companions show the expected fluctuations in light and velocity, including GP Velorum = Vela X1 and V884 Scorpii, but quantitative matches with tidal theory remain unrealized.

Other variation mechanisms

While eruptive and pulsating stars vary due to a variety of dynamical, thermal and cyclic instabilities that are more or less understood, or at least largely identified, variations in many categories are caused by instabilities that are not so well understood, by random events and by random drifts in conditions. Some of these stars live on the border between intrinsic and extrinsic variables. For example, RS CVn, BY Dra and W UMa binaries can be heavily covered by magnetic spots, similar to sunspots. The agent understood to produce such spots is dynamo action in a fast-rotating convective envelope, so cool stars that have convective envelopes are likely candidates—if they spin fast. The RS CVns, BY Dras, and W UMas naturally spin fast because they are tidally locked close binaries, but FK Com and a small number of similar stars are fast spinning *single* giants! Their fast rotation currently is attributed to their being recently merged ex-binary systems, with the binary orbital angular momentum now existing as spin angular momentum. Spot-modulated stars are extrinsic variables in that they vary on the orbital time scale because of changing aspect of their spots. However, the spots grow, decline and move, so they are intrinsic variables on longer time-scales.

Accretion tends to be highly irregular and causes not only modest brightness fluctuations in active binaries, but variations of up to several magnitudes in newly formed stars that accrete from their surroundings (T Tauri stars). Much of the luminosity of T Tauris and related stars is from the accretion process. Young objects of the FU Orionis type have brightening episodes of up to five magnitudes on a time-scale of decades to centuries. Outflows are associated with accretion but are not well understood at present. Some classical T Tau stars are surrounded by circumstellar disks that have been imaged in the infrared, with spectroscopic and imaging evidence of bipolar outflows. Accretion onto white dwarfs not only leads to circumstances that eventually produce nova explosions but also directly converts gravitational energy to more tangible forms, as seen above for dwarf novae. Even an occasional non-degenerate binary such as V361 Lyrae has a hot spot where high-speed gas impacts one of the stars, having flowed in a well defined stream from the other. Variable flows produce variable spot luminosities and thus another kind of intrinsic–extrinsic variable. In post novae and dwarf novae, the hot spot is on a disk surrounding the stream's target star. Most exploding stars show variability between outbursts in their 'quiescent' light curves. A common seat of variation is the hot spot as it flickers by $0.^m1$ to $0.^m2$ on a time scale of minutes, due to irregular inflow. Usually the hot spot itself, rather than either star or the overall disk, is the brightest light source in the binary. X-ray binaries whose accreting objects are neutron stars have accretion power at least 30 times their thermonuclear power (for H burning; more than 100 times for He burning), so the promptly released energy is about the same whether the material burns or not. However, large thermonuclear bursts can occur on neutron stars if substantial amounts of fuel accumulate, providing the sources known as x-ray bursters, where helium is the fuel. As a group, x-ray binaries are variable in all spectral regions, from radio to gamma, although most individuals are detected only in restricted ranges. There are two essentially disjoint classes on greatly different scales, low-mass x-ray binaries (LMXBs) and high-mass x-ray binaries (HMXBs). At first inspection, LMXBs and HMXBs have little in common except that they contain neutron stars, and even a sketch of ideas about their origins would exceed available space. Configurations are such that HMXBs accrete mainly via winds from their blue supergiant companions and many pulse in x-rays, while LMXBs accrete mainly via lobe overflow and very few pulse. LMXBs bear a remarkable similarity to CVs, including absolute dimensions, with the notable difference being that a neutron star replaces the CV's white dwarf. It has been noted that some LMXBs may form from CVs in rare cases of accretion beyond the white dwarf mass limit.

Still another kind of intrinsic–extrinsic hybrid is the *symbiotic star*, where ultraviolet radiation from the environs of a small, hot accretor interacts with the wind, extended atmosphere or chromosphere of a red giant companion. Fluctuations in UV radiation and in wind flow lead to intrinsically variable fluorescence modulated by orbital aspect effects, sometimes including eclipses. Orbit periods are long compared with most variable binaries, being typically hundreds of days or more. Because of observational difficulties, the defining characteristics of the class are necessarily superficial—the accreting objects are not usually directly observed and may be as diverse as neutron stars, white dwarfs and main sequence stars. Extreme examples of symbiotics include *symbiotic novae* that have outbursts by brightness factors of order 100 and are believed to contain white dwarf accretors. Unlike CVs, a symbiotic nova can be in outburst for decades. The mechanism usually assumed is a thermonuclear surface flash on the accretor followed by slow cooling. These objects are often called slow novae but differ radically from the CVs with the same name, so 'symbiotic nova' should consistently be applied. Examples of symbiotic novae include PU Vulpeculae, RR Telescopii and V1329 Cygni.

Variable polarization can result from scattering by circumstellar gas, but really spectacular variable polarization is seen in CVs that contain accreting white

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

dwarfs with extremely strong magnetic fields. These are the *polars*, or AM Her binaries, where cyclotron radiation in an oblique rotator produces strong circular polarization over a wide range of wavelength, including optical light. Polars also are moderately strong x-ray sources and natural laboratories for studying hydrodynamic flows under combined gravitational and magnetic fields, with variable light and polarization as diagnostics. *Intermediate polars* have magnetic fields that are intense but somewhat below those of polars. Examples of intermediate polars are EX Hydrae and GK Persei.

Fluctuations in stellar winds can generate small-scale emission line and continuum variation, particularly where winds are strong. Most *Wolf–Rayet* (W–R) stars accordingly vary by a few hundredths of a magnitude. A W–R star is the highly evolved residue of a very massive star that has lost much of its envelope so as to expose hot inner regions. Often there is an evolved close companion with its own strong wind, so that wind–wind interactions cause further variation.

Intermittent veiling is a very unusual variation mechanism and a major diagnostic of circumstellar conditions and interior structure in certain (usually giant) stars. In veiled stars we find intrinsic and extrinsic variation combined, as clouds come and go while changing aspect controls their influence on light curves. Hydrodynamic flow in a mass transferring binary can lead to concentrations of partially opaque material being projected onto the face of one or both stars, so that light curves can help map circumstellar gas. An example is AX Monocerotis. Particularly spectacular examples of veiling are the *R Coronae Borealis stars*—extremely carbon rich and hydrogen deficient (apparently single) supergiants that are veiled by carbon particles at irregular times, with brightness drops by factors of up to about 1000. These pulsating stars eject clouds of gas whose carbon condenses to soot when sufficiently far from the hot photosphere, with clouds that happen to lie on the line of sight producing the veiling. Pulsational characteristics, together with the strange abundances, provide strong constraints on possible evolutionary histories of R CrB stars. Given that only a few dozen are known, R CrBs must either represent a very brief stage of normal evolution or products of an unusual formation process such as a merger.

Large evolutionary changes over the brief history of observational astrophysics are extremely unusual. Perhaps the most spectacular example is FG Sagittae, which has evolved from the small, hot exciting star of a planetary nebula into a pulsating R CrB type red giant in only a century, with decade to decade developments. Whether FG Sge is typical as a progenitor of R CrBs is an open issue at present.

Flares are brief local eruptions, prominent in both continuum light and lines, from the chromospheres of magnetically active stars. The *UV Ceti* or *flare stars* are low-mass main sequence stars with unusually high levels of chromospheric activity. Flares are much hotter than red dwarf photospheres, so the brightening in magnitudes is highly wavelength dependent, increasing strongly into the ultraviolet. As with spot-modulated stars, rotation in a deep convective envelope generates strong dynamo action, with UV Cet stars being especially fast rotators. Flare activity is at least statistically a sign of youth, since red dwarf rotation decreases with age.

Stars described as variable are traditionally those that vary in brightness, especially over broad spectral regions. However, several kinds of *spectrum variables* vary most notably in spectral details, with behavior that can be as interesting as in the more obvious variables. For example, strong variable magnetic fields are involved in spectral variations of Ap and Am stars (Ap = peculiar stars of spectral type A; Am = metallic line stars of spectral type A). Stars that lose matter via powerful and unsteady winds, such as those of spectral type Of, show variable emission lines with great Doppler broadening. Stars of type Be (*B emission stars*) were among the first to draw special attention as spectroscopically interesting in the 1800s, and continue to stimulate hypotheses, observations, and controversy. The emission lines of Be stars are usually ascribed to circumstellar equatorial rings associated with centrifugal ejection of matter, but circumstances leading to that situation are not widely agreed upon. Even the basic point of whether binary nature is essential or irrelevant to Be behavior remains at issue.

Unique objects

Much of the fascination of variable star astrophysics is provided by unique objects that may result from anomalous formation, short effective lifetime or selection effects. A few examples may give some of the flavor.

Most recognized causes of variation, including pulsation, gas dynamic interactions and rotation phenomena, have been proposed for the spectacular and mysterious η Carinae. Especially notable are its great luminosity and enormous swings in apparent magnitude over centuries, including an interval in the 1840s when it approached Sirius in brightness. It is usually regarded as a supermassive star with mass above (and perhaps far above) 60 solar masses, and therefore a candidate for core pulsation via unstable thermonuclear burning. Speculation that it is a binary is supported by recent high resolution imaging of a bipolar nebula that must have been ejected in η Car's great outburst of *c*. 1840 and by discovery of 5.5 year spectroscopic and photometric periodicities. Understanding of η Car is rapidly developing but still rudimentary.

The recurrent nova T Corona Borealis has the basic red star–blue star binary morphology of novae, but with a red giant in place of the usual main sequence red star and

an orbit period (228^d) typical of symbiotic novae. However, it can scarcely be called a symbiotic nova, as the outbursts last not for decades but only for weeks. T CrB has no known siblings, but does have a rich and extensive literature.

And then there are the pulsating WHITE DWARF stars, the DUSTY CIRCUMSTELLAR DISKS, the QUASIPERIODIC OSCILLATIONS IN X-RAY BINARY STARS, the incredible SS433 and HERCULES X-1, …, but wait—those are other articles. No brief synopsis could do them justice. So turn to those articles—your instrumentation is a comfortable chair and a cup of hot chocolate. Enjoy.

Vatican Observatory

The Vatican Observatory is one of the oldest astronomical institutes in the world. It began with the reformation of the calendar in 1582. At the Roman College, Father Angelo Secchi first classified stars according to their spectra. With these rich traditions Leo XIII, in 1891, formally founded the Vatican Observatory on a hillside behind the dome of St Peter's Basilica. In 1935 Pius XI provided a new location for the Observatory at the Papal Summer Residence at Castel Gandolfo. In 1981 the Observatory founded a second research center in Tucson, Arizona. In 1993 the Observatory, in collaboration with STEWARD OBSERVATORY, completed the construction of the Vatican Advanced Technology Telescope (VATT) which has pioneered the new technology of creating large, lightweight, stable mirrors in a rotating furnace. Research includes cosmological models, spectral classification of peculiar stars, photometric studies of metallicity, mass-exchanging binary stars, material in star-forming dark clouds, dust envelopes about young stars, planetary dynamics. The Observatory is supported with an annual budget from the Holy See and by contributions to the Vatican Observatory Foundation, a tax-exempt corporation in the State of Arizona.

Vega

The star α Lyrae, the only bright star in the constellation. Its name, formerly Wega, derives from the Arabic *Al Waki*, 'the Swooping (or Falling) Eagle', hence the form Alvaka used on some seventeenth century celestial globes. In ancient Greek and Latin writings it sometimes shared the constellation name Lyra, and consequently appears as 'the Harp Star' in some later texts. It is the dominant component of the Summer Triangle asterism, with Altair and Deneb. It was the Pole Star about 12 000 years ago, and will be again 14 000 years hence.

Vega is the fifth brightest star in the heavens, with an apparent magnitude of 0.03. It is the brightest star with sufficiently high northern declination to appear overhead in north temperate latitudes, and dominates their skies on clear summer nights. It is a striking object when viewed with binoculars or a low-power telescope, its blue-white color (sometimes described as 'sapphire') belying its relatively cool spectral type (A0Vvar). Fairly close at 25.3 light-years distance (parallax 0.129″), Vega is in fact the third closest of the bright stars. Its absolute magnitude is 0.6. In 1983 it was discovered by the IRAS survey to be surrounded by a disk of gas and dust, which may eventually form a planetary system.

VEGA Space Mission

VEGA (mission) is a combined spacecraft mission to VENUS and COMET HALLEY. It was launched in the USSR at the end of 1984. The mission consisted of two identical spacecraft VEGA 1 and VEGA 2. VEGA is an acronym built from the words 'Venus' and 'Halley' ('Galley' in Russian spelling). The basic design of the spacecraft was the same as has been used many times to deliver Soviet landers and orbiters to Venus. In June 1985, these spacecraft successfully delivered the first balloons into the Venus atmosphere and also landers. After this the VEGA 1 and VEGA 2 cometary probes were directed to the comet Halley. They encountered it on 6 and 9 March 1986. Such a trajectory was possible only because of the favorable mutual positions of the comet and Venus at this time. The gravitational field of Venus turned the spacecraft to the comet and only a short switch-on of the spacecraft engine was necessary.

The most important scientific achievements of the VEGA mission were as follows: (a) the first direct tracing of Venusian atmospheric properties (winds, turbulence, illuminance, cloud density) on a long horizontal path; (b) the first look at a cometary nucleus, not as a star-like object, but as a spatially resolved body; (c) the first identification of a set of components of the cometary atmosphere, including organic matter; (d) the first study of the cometary environment by direct (contact) methods. The VEGA mission was an important step in the development of international cooperation in space studies. Scientists and engineers of many countries were involved together with Russians in the creation of sophisticated scientific instruments and supporting systems. Such international cooperation in a space project was new not only for Russia. Professor R Sagdeev (leader then of the Institute of Space Research in Moscow) was the head of the whole project, and these innovations were in many points results of his enlightened activity.

Venus

Balloons

The launch of balloons with meteorological instruments is traditional in studies of the terrestrial atmosphere. It is natural to apply this for atmospheres of other planets. The concept of a Venusian balloon was first proposed by J Blamont in 1967, but only after 18 yr of technical studies (in the USSR and France) was it realized in the VEGA mission.

The Venus module of the VEGA spacecraft entered the atmosphere of the planet and separated into two parts at a height of 64 km. One of them was a descent probe (lander) and the other was a canister containing balloon, ballast, parachute and inflating systems. Beginning at 64 km the container went down with the parachute to about 50 km (where the atmospheric pressure is near 1 bar); there the balloon was inflated, and parachute and ballast separated. After this balloon went up to about 53.6 km corresponding to a pressure of 535 mbar and a temperature of 305 K. Both balloons were inserted on the nightside of Venus, one (VEGA 1) $\sim 7^\circ$ north of the equator and the other $\sim 7^\circ$ south of the equator. They drifted westward with the predominant zonal wind closely parallel to the lines of latitude. Each balloon was tracked over a distance of more than 11 000 km, encountering dawn and then penetrating far into the daylit atmosphere (figure 1(D)). Transmission was stopped after 46 h of flight owing to limited battery resources.

There were two types of measurements: *in situ* by means of on-board instruments transmitted by telemetry and ground-based determination of balloon motion by very-long-baseline interferometry (VLBI). The balloon's transmitter sent directly to the Earth signals at a wavelength of 18 cm used ordinarily by VLBI astronomers for observations of distant galactic OH sources. Because of Earth's rotation, continuous reception of telemetry data required the use of many antennas widely distributed in longitude.

It was known earlier that so-called superrotation is the dominating dynamical property of Venus' atmosphere: its rotation period (about 4 days near cloud top) is much shorter than for the solid surface. This means that a fast westward wind is a permanent feature on Venus (see VENUS: ATMOSPHERE). VEGA balloons provided its mean velocity (67–69 m s^{-1}) and its fine fluctuation pattern also.

Strong turbulence was found with amplitude to 2 m s^{-1} with a time scale of 30–100 s (figure 1(C)). The influence of surface topography on atmospheric motions was found; it was not expected for such high altitudes. The measurements covered the twilight zone which was found to be 7° wide in the clouds of Venus. The horizontal profile of the clouds' optical properties (backscattering coefficient) was measured for the first time. It was found that at the height of flight it is smooth in general; even the strongest variations were no more than a factor of 3 from the average level (figure 1(E)). Such an experiment has not yet been repeated; however, balloons are present in many proposals for future studies of the atmospheres of Venus and Mars.

Descent probes

Studies of Venus by means of descent probes were started by the VENERA 4 mission in 1967. Another 10 Soviet VENERA MISSIONS followed during 1969–1983; eight of them included descent probes with instrumental packages that provided measurements of the chemical composition of the atmosphere and soil, images of the landscape around landers, vertical profiles of temperature and pressure, the cloud particles' properties and solar illuminance within the deep atmosphere of Venus. VEGA 1 and 2's descending probes landed on the nightside of the planet, unlike most of the previous descenders, but the general scheme was traditional: entry to the atmosphere, fast aerodynamic deceleration of capsule with descenders between 100 and 64 km, opening of capsule, about 10 min of descent to 46 km, separation of parachute, landing after about 51 min and 20 min of working data transfer from the surface.

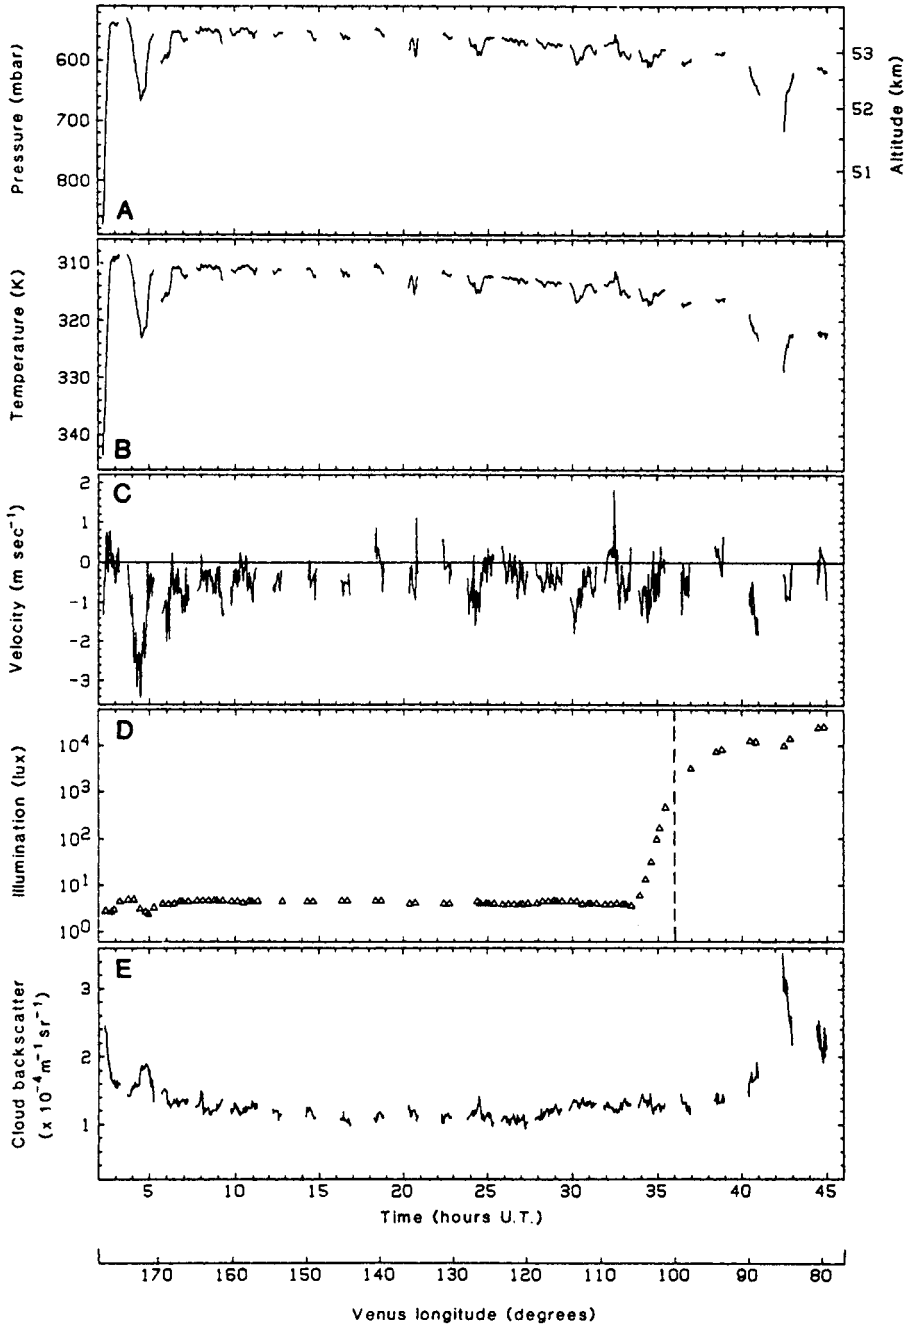

Figure 1. Mission history for VEGA 1 balloon showing (A) pressure, (B) temperature, (C) atmospheric vertical velocity, (D) ambient light level and (E) cloud backscatter coefficient as functions of time after insertion on 11 June 1985. Venus longitudes are also shown on the abscissa. The approximate position of the terminator is shown as a broken line in the plot (D). Gaps in the data sets indicate times when no *in situ* measurements were transmitted by the balloon (Sagdeev *et al* 1986b).

Improved measurements of atmospheric temperature were made in the full range between ∼63 km and the surface. The temperature rises monotonically from up to down but an inversion was found near 61 km. The lapse rate is not constant; its variations confirmed the existence of two convective zones, one below 15 km, another between 45 and 58 km (unlike our planet where only one convective zone exists, between ∼10 km and the surface).

Cloud particles were studied in different ways with a set of sensors that measured size distribution, number density and chemical composition. Sulfuric acid (H_2SO_4)

as one of the constituents of the Venusian cloud particles was detected by *in situ* measurements. This compound dominates the upper and probably the middle clouds (down to 54 km) but below this level cloud particles mostly consist of a phosphorus compound (probably H_3PO_4).

A UV lamp and spectrometer were used to study the strong UV spectral band created by small traces of SO_2 which was found by earlier probes by another method (gas chromatography). Analysis of the new measurements confirmed the presence of SO_2 but gave different quantities and covered larger height ranges.

Measurements of soil composition were made after landing by two methods. One of them (x-ray fluorescent spectrometry on VEGA 2) showed that elemental composition is like that of very ancient lunar rocks (see also VENUS: SURFACE). Another (based on K, U and Th abundances) in both places showed rocks like toleit basalts.

The VEGA descent probes were the last in a long set of Soviet VENERA missions but most of the studies resulted in new questions that require new experiments. However, it is impossible to say at the moment where and when new steps will be made for prolongation of the study of Venus.

Comet Halley

COMETARY NUCLEI are probably samples of pristine solar system material and their study may be important for an understanding of the origin of the solar system. However, they are practically not available for observations from the Earth; only products of their evaporation (coma and tail) are observable. Spacecraft give a unique possibility of approach to the cometary nucleus and investigation of it as a spatially resolved object. Comet Halley was selected for the first try. At every periapsis passage (once per 76 yr) it is available for astronomical observations but the relative position of the comet and Earth is not same in different apparitions. For example, the passage of 1986 was not favorable, because the comet periapsis point and Earth were nearly in opposite directions from the Sun. So it was reasonable to use spacecraft during this apparition. Comet Halley was especially attractive for such a mission because it is a periodic comet with a well-known orbit, it is the brightest among the periodical comets and it is the only periodic comet having physical properties like those of a young comet.

In reality not one but five spacecraft were sent to the comet Halley: Soviet VEGA 1, VEGA 2, European GIOTTO and Japan SUISEI and SAKIGAKE. The VEGA cometary probes were the largest and had more scientific instruments than the European and Japanese craft put together. The mass of every VEGA spacecraft (figure 2) was about 4500 kg, including about 2500 kg for the cometary module. There were two sorts of experiments on VEGA cometary modules: (a) camera and other optical instruments for remote sensing studies of the nucleus and inner coma and (b) instruments for contact measurements in cometary gas, dust and plasma. Imaging of the comet from the spacecraft required a steerable platform which could be

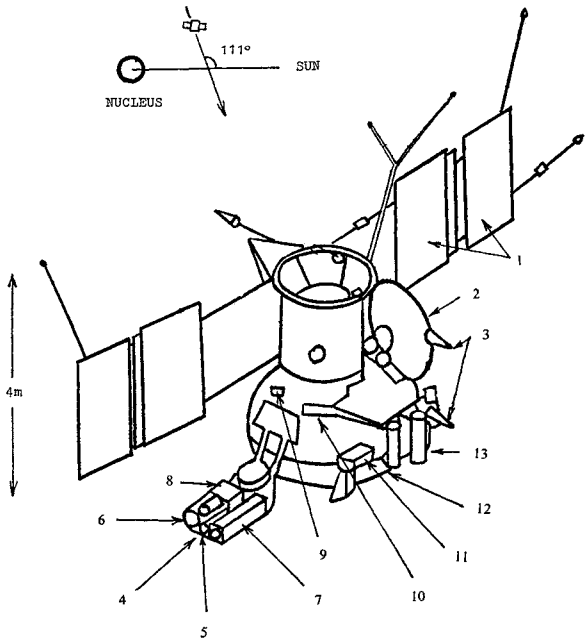

Figure 2. The Halley probe of the VEGA spacecraft , showing the locations of some subsystems and scientific instruments: 1, solar panels; 2, pencil-beam antenna; 3, omnidirectional antenna; 4, steerable platform; 5, the pointing sensor; 6, camera system TVS; 7, infrared spectrometer IKS; 8, ultraviolet–visible–near-infrared spectrometer a; 9, dust particle sensor SP-1; 10, particle composition analyser PUMA; 11, plasma composition analyser PLASMAG; 12, dust protection shield; 13, astro-orientation unit. The Venus probe is not shown. Its location before separation is on the top of the Halley probe.

automatically pointed with high accuracy to the cometary nucleus. A TV camera, IR spectrometer and UV–Visible–near-IR spectrometer were placed on this platform. The most difficult task was to locate the nucleus, with its low albedo, against the background of the bright coma with gas and dust jets, and this problem was solved successfully. The fly-by speed was extremely high ($\sim$78 km s^{-1}), because the direction of orbital motion of the comet is opposite to that of the Earth, and thus of the spacecraft. This high speed resulted in a strong dust hazard and required protection of parts of the spacecraft.

VEGA 1 passed through the comet Halley coma on 6 March 1986 at a nearest distance to the nucleus of 8890 km, VEGA 2 did it 3 days later at a distance of 8030 km. Most of the data were sent to Earth in real time , because loss of the spacecraft due to the dust hazard was possible. However, this did not happen; both of the spacecraft were alive after the fly-by, although the solar-battery current dropped by 50%. Figure 3 shows how comet Halley looked from the spacecraft VEGA 2 on 6 March 1986. Results of the analysis of images, spectra, and *in situ* data obtained are briefly outlined below.

It was concluded that the nucleus is a single solid body. Its shape is irregular (like a potato); the size is approximately 8 km $\times$ 8 km $\times$ 16 km. It has a very low

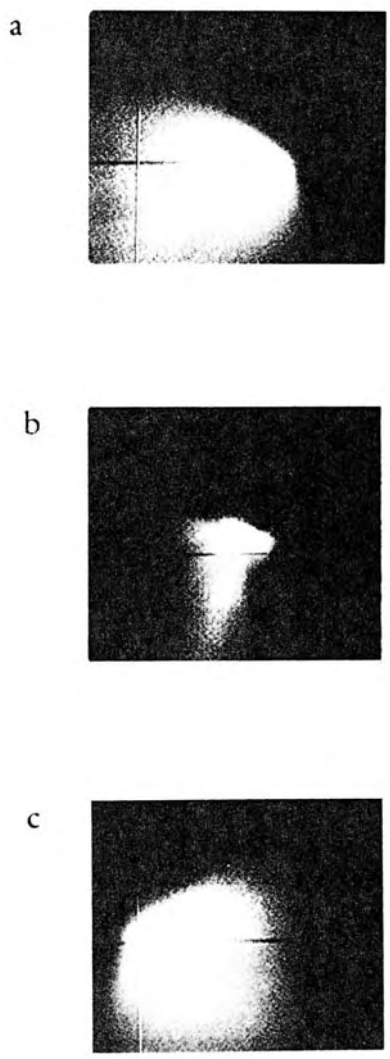

Figure 3. How comet Halley looked from spacecraft VEGA 2 flying through its coma. (*a*) The distance to the nucleus $d = 29\,000$ km, the Sun is on the left, the nucleus is near the right edge of the bright dust fan directed towards the Sun; the frame size is 228 km × 308 km. (*b*) $d = 8000$ km, the Sun is above the plane of the image (phase angle ∼30°), the frame size is 62 km × 84 km; the upper part of the visible spot is the nucleus, the lower is a dust jet. (*c*) The Sun is to the right, the nucleus is to the left; the distance and size are the same as in (*a*). (Moroz 1989).

reflectivity; the geometrical albedo is ∼0.04. So it is one of the darkest bodies of the solar system. Dust is emitted by its surface from the sunlit side. The dust flow consists mainly of narrow jets. The thermal IR radiation of the nucleus was measured by an infrared device. Its value corresponds to a temperature of about 380 K near the subsolar point. This was unexpected because a lot of water ice with a temperature about 200 K should exist in the upper layers of the nucleus to provide the H_2O flux observed by the same instrument and also in many other experiments. This discrepancy may be explained by a patchy structure of the surface (icy and rocky patches) or by a porous mantle which may be hot on the upper boundary and cold on the lower. The mass of nucleus was estimated as 3×10^{14} t and density about 0.6 t m^{-3}.

Indirect estimates of the chemical composition of the nucleus are possible on the basis of measurements of the chemical composition of gas and dust going out from the nucleus surface to the coma. H_2O was identified as the most abundant constituent with a production rate of about 10^{30} molecules s^{-1}. Organic substance outflow (never observed earlier) was identified using IR spectra obtained by VEGA 1. Its production rate may be comparable with that of H_2O. CO_2, CO and HCHO were observed with same instrument as parent species with mixing ratios of a few per cent. It is important that mainly secondary components arising from the decay of such parent molecules were observed earlier from the Earth. Detailed observations of secondary species with the VEGA spacecraft revealed their production rates, geometry of ejection, lifetimes of species and their parent and species velocities.

Neutral atoms and molecules in the coma are converted to ions by photoionization. The SOLAR WIND when it encounters them creates a shock wave that was met by the spacecraft at a distance of $\sim 10^6$ km from the nucleus. Nearer, at a distance $\sim 10^5$ km, another characteristic boundary (not predicted by theory) was met; later it was called the 'cometopause'. Cometary ions dominate the plasma inside this. The plasma composition, its energy distribution, plasma waves and magnetic fields were measured.

Grains of different masses (from $\sim 10^{-19}$ to $\sim 10^{-11}$ kg) were counted by a few VEGA instruments. The dust mass production rate was estimated. One of the instruments provided measurements of the chemical composition of individual particles and showed its large diversity. Some of them contain simultaneously C, H, O, N as was predicted for interstellar particles; others are icy, silicate or metallic bearing. Very small particles ($<10^{-14}$ g) are dense (1 and 2.5 g cm^{-3} for organic and silicate particles, respectively), while optically active particles ($>10^{-10}$ g) are of low density (0.3 g cm^{-3}) and of a complicated structure.

VEGA's flight to comet Halley was an important part of coordinated international efforts giving a very strong impulse to studies of comets and other small bodies of the solar system.

Vela

(the Sails; abbrev. Vel, gen. Velorum; area 500 sq. deg.) a southern constellation which lies between Antlia–Pyxis and Carina, and culminates at midnight in mid February. It was introduced by the French astronomer Nicolas L de Lacaille (1713–62), who charted the southern sky in 1751–2, from stars that formed part of the ancient constellation of Argo Navis (the Ship), which had been included by Ptolemy (c. AD 100–175) in the *Almagest*.

The brightest stars in Vela are γ Velorum (Regor), a multiple system consisting of the brightest Wolf–Rayet star in the sky (bluish-white, WC8 + O9, range 1.81–1.87) and a bluish-white (B2) component, magnitude 4.3, separation 41″, the former of which has an unseen companion that revolves around it in 78.5 days, and a fourth, bluish-white (B6) component, magnitude 7.7, separation 63″, δ Velorum, a very close binary with a white (A1) primary, magnitude 2.0, and a fainter secondary, magnitude 5.6, separation 0.74″, λ Velorum (Suhail), magnitude 2.2, κ Velorum (Markeb), magnitude 2.5, and μ Velorum, another binary, with yellow (G5 and G2) components, magnitudes 2.9 and 5.9, separation 2.0″. There are nine other stars brighter than magnitude 4.0. δ and κ Velorum together with ι and ε Carinae make up as asterism called the False Cross, as it is sometimes confused with the constellation Crux (the Southern Cross).

The Milky Way passes through Vela and the constellation contains more than 40 open clusters and many planetary nebulae, including IC 2391, an open cluster of more than 20 stars scattered across a 1° field, the brightest of which is *o* Velorum, magnitude 3.6, and NGC 3132 (the Eight-Burst Nebula), a ninth-magnitude planetary nebula with a tenth-magnitude star at its center. Other interesting objects include NGC 3201, a seventh-magnitude globular cluster, and the vast Gum Nebula, an expanding emission nebula some 36° across that extends into the neighboring constellations of Antlia, Pyxis, Puppis and Carina, and is thought to be the result of a supernova explosion that occurred more than 1 million years ago, inside which is the more recent Vela supernova remnant and at its center the Vela pulsar.

Vela Pulsar

The pulsar PSR 0833–45, discovered in 1968. With a period of only 9.3 ms, it has one of the fastest pulse-rates known, implying that it is one of the youngest pulsars. This is borne out by an observed deceleration in its pulse-rate of 10.7 ns per day, which sets an upper limit to the time elapsed since it was formed in a supernova explosion of about 11 000 years. In 1977 its pulsations were also recorded in visible light, making it one of the first optical pulsars to be confirmed.

The Vela pulsar is located in the southern Milky Way, 2.8° south of the galactic equator and approximately at the centre of a triangle formed by the stars ζ Puppis, γ Velorum and λ Velorum. It is surrounded by extensive nebulosity more than 5° across, also a product of the supernova, and is associated with a moderately strong radio source, Vela X; its distance has been estimated at between 1300 and 1600 light-years. The Vela pulsar and supernova remnant lie within a much older and larger supernova remnant, the Gum Nebula.

Vela Supernova Remnant

A supernova remnant in the constellation Vela, position RA $08^{h}\ 34^{m}$, dec. $-45^{\circ}\,45'$. It extends to nearly 5° in diameter, and consists of material expelled by a supernova an estimated 11 000 years ago. The core of the supernova remains as the Vela Pulsar.

Velikovsky, Immanuel (1895–1979)

Physician, psychoanalyst, cosmologist and writer, born in Vitebsk, Russia. His book *Worlds in Collision* claimed from analysis of mythology and scientific fragments that a breakaway piece of the planet Jupiter had collided with the Earth, causing various disasters recorded in the Bible, and ending as the planet Venus. None of his theories stood up to analysis and further exploration.

Venera (Missions)

Veneras 1 to 16 are the Russian (Soviet) spacecraft missions to VENUS launched in the period 1961–1983 (table 1). Venus was also studied by the VEGA MISSION.

The first three Venera (hereafter V) missions, V1–V3, were developed by the space center headed by Sergey Korolyov, father of the Russian space industry (1906–1966). (This space center is now a division of the Energia Association.) Since 1967, spacecraft for missions to planets have been developed by the Lavochkin Association. V1–V8 are the first generation of the Venera spacecraft. The spacecraft mass varied from 900 to 1200 kg. The three-stage Soyuz missile, with the first two stages similar to those used for the first manned flights to space, launched a spacecraft and the fourth stage into Earth orbit. Then the fourth stage accelerated the spacecraft and moved it into the interplanetary orbit to Venus. Due to the insufficient reliability of the fourth stage and some subsystems in the early 1960s, some spacecraft were lost or their programs were not completed in full. However, the first generation spacecraft made the first soft entries into the atmosphere and landed on the surface of Venus.

V9 to 16 (and also Vega 1 and 2) represent the second generation of missions to Venus. Their mass was 5000 kg, and they were launched by the Proton rocket. Those missions were successful, reliable and, along with ground-based observations and the USA Mariner 2, 5 and 10, Pioneer Venus and Magellan spacecraft, they provided the basis of our current knowledge of Venus.

Scientific objectives

The objectives of these missions were to study (i) the surface relief and properties of rocks, (ii) the thermal structure and chemical composition of the lower atmosphere ($h < 65$ km), (iii) the atmosphere and ionosphere above the cloud layer ($h > 65$ km), (iv) the magnetic field and plasma environment near Venus, and (v) the solar wind, interplanetary magnetic field, cosmic rays and micrometeorites during the cruise phase.

Scientific instrumentation

V2. Magnetometer, plasma detectors, cosmic ray and micrometeorite sensors, telecamera, infrared (5–40 μm) and ultraviolet (1700–3500 Å) spectrometers, radiometer in the decimeter range. Only some data during the cruise phase were obtained.

V3. *Flyby:* magnetometer, plasma detectors and cosmic ray sensors, photometer at H 1216 Å and O 1304 Å. *Lander:* atmospheric temperature, pressure and density sensors, chemical gas sensors, photometer, γ-ray counter. Only some data during the cruise phase were obtained.

V4. The same as V3 with an altimeter instead of the lander photometer. *Results:* the first entry and direct measurements in the atmosphere down to $h = 23$ km. Pressure at 55–33 km, density at 55–28 km, temperatures at 55–23 km, atmospheric composition ($CO_2 > 90\%$, $N_2 < 7\%$). Hydrogen corona, upper limit to atomic oxygen density, plasma bow shock at 19 000 km from the planet, low density of the nightside plasma, magnetic moment ($< 3 \times 10^{-4}$ of the Earth's value).

V5, 6. Measurements of pressure, density and temperature (p, ρ, T, respectively) at 55–17 km, chemical gas sensors.

V7. First soft landing on Venus. Measurements of T from 55 km to the surface.

V8. p, ρ, T from 55 km to the surface, radar altimeter for determination of altitude, photometer to study the light conditions and the cloud structure (the lower cloud boundary was observed at 33 km), measurements of wind speed using the Doppler shift of the radiotransmitter frequency, γ-spectroscopy of the surface rocks.

V9, 10. *Lander (1560 kg):* γ-spectrometer, γ-densitometer, p, T sensors, camera, accelerometer (p, T at 90–65 km), mass spectrometer, nephelometer (angles of 4, 15, 45 and 175°), photometer for five broad intervals in the range 0.44–1.16 μm, narrow band photometer for 0.8, 0.82 and 0.87 μm (continuum, H_2O and CO_2 bands, respectively), onboard transmitter (Doppler measurements of wind speed). *Orbiter:* imaging system (0.3–0.4 μm), spectrometer (0.24–0.75 μm), IR spectrometer (1.7–2.8 μm), IR radiometer (8–28 μm), multiband photopolarimeter (0.35–0.8 μm), photometer at H 1216 Å with absorption cells, magnetometer, plasma electrostatic spectrometer, plasma sensors, cosmic rays, dual-frequency onboard transmitter (radio occultations and bistatic radar).

V11, 12. *Lander:* p, T sensors, accelerometer, mass spectrometer, gas chromatograph, optical spectrophotometer (0.45–1.2 μm), nephelometer, x-ray fluorescence spectrometer, low-frequency electromagnetic detector, onboard transmitter (Doppler measurements of wind speed). *Flyby:* ultraviolet spectrometer (304–1657 Å), plasma sensors, cosmic rays, γ-ray bursts.

V13, 14. Color camera, rock sampling, penetrometer, electric conductivity of rocks, x-ray fluorescence spectrometers for (a) rocks and (b) aerosols, p, T sensors, accelerometer, mass spectrometer, gas chromatograph, spectrophotometer (0.32–1.2 μm), electromagnetic and microseismic detectors, electric conductivity of aerosol, onboard transmitter (wind speed measurements), γ-ray bursts (cruise).

V15, 16. Synthetic aperture radar, radio altimeter, Fourier transform spectrometer (5–40 μm), dual-frequency onboard transmitter (radio occultations).

Main scientific results

Relief. Detailed mapping of the Venus relief was made with the synthetic aperture radars and radio altimeters (V15, 16). This study covered the vast area north of about 30° that is about a quarter of the total surface of Venus. This mapping had a spatial resolution of 1–2 km, which is sufficient to distinguish various landforms and terrains and determine the geological processes responsible for their formation. This resolution is better than that of 20 km in a similar study from the Pioneer Venus orbiter in 1979

Table 1. Venera 1 to 16 missions.

#	Launch	Encounter	Comment
1	12/02/1961	—	First interplanetary spacecraft; flyby 100 000 km
2	12/11/1965	27/02/1966	Flyby 24 000 km
3	16/11/1965	01/03/1966	First hard landing
4	12/06/1967	18/10/1967	First soft entry (to 23 km) and flyby
5	05/01/1969	16/05/1969	Soft entry (to 17 km)
6	10/01/1969	17/05/1969	Soft entry (to 17 km)
7	17/08/1970	15/12/1970	First soft landing
8	27/03/1972	22/07/1972	Soft landing
9	08/06/1975	22/10/1975	Soft landing and first orbiter $h_{\min} = 1560$ km
10	14/06/1975	25/10/1975	Soft landing and orbiter $h_{\min} = 1620$ km
11	09/09/1978	21/12/1978	Soft landing and flyby at 40 000 km
12	14/09/1978	25/12/1978	Soft landing and flyby at 40 000 km
13	30/10/1981	01/03/1982	Soft landing and flyby
14	04/11/1981	05/03/1982	Soft landing and flyby
15	02/06/1983	10/10/1983	Orbiter $h_{\min} = 1000$ km
16	07/06/1983	14/10/1983	Orbiter $h_{\min} = 1000$ km

but not so good as the 0.12 km achieved by the Magellan orbiter seven years later (1990–1994).

The Venus surface (see VENUS: SURFACE) is dominated by plains formed by vast floods of the non-viscous volcanic lavas, probably basalts. About 15% of the mapped area is covered by so-called tessera, which is a specific terrain formed by heavy tectonic deformation of some unknown precursor terrain. The morphology of numerous ring-like volcanic plain features, so-called coronae, is evidence of their formation due to tectonics and volcanism related to the uplifting plumes in the planet's interior. Several large fracture zones sharing many properties with the continental rift zones on Earth were found. Many impact craters of 8 to 150 km diameter show the age of the mapped area to be 0.5–1 billion years. The main conclusion is that the geology on Venus, contrary to that on Earth, is not driven by plate tectonics.

Panoramas of the landing sites of V9, 10 (figure 1), 13 and 14 show the small-scale structure of the surface. Of four sites, only two are similar (V10 and 13). V9 shows a slope of the mountain ridge covered by irregular and sharp-edged stones having sizes up to 0.5–0.7 m. V10 and 13 landed on the rolling plain with outcrops of crystallized magmatic rocks changed by deep chemical weathering. Steeply sloped uplands with layered structured rocks are seen sloping away. V14 found a smooth region of the stone plain (lowland) composed of relatively fresh fine-grained rocks having a horizontal layered structure which resembles the accumulation of volcanic tuff.

Composition of rocks. The abundances of Mg, Al, Si, K, Ca, Ti, Mn, S, Cl and Na given as their oxides were measured by the x-ray fluorescence spectrometers at the V13, 14 and Vega 2 landing sites. Abundances of the natural radionuclides (K, U, Th) were measured by the gamma-ray spectrometers from V8, 9, 10, Vega 1 and 2. Both elemental and radionuclide abundances are typical of various types of erupted basalts, with the exception of V8 which is more similar to granites.

Mechanical properties of rocks. The density of rocks was measured by the gamma-ray densitometer from V10 to be 2.8 ± 0.1 g cm^{-3}, which is typical of crystalline basalts. Determinations of the bearing strength and firmness of rocks were made by V13 and 14 using three methods: (i) a penetrometer which impacted the ground, (ii) sampling the rocks by drilling for the x-ray fluorescence analyses, and (iii) accelerometer observations during the shock of landing. Heavy clays and compacted dust-like sand are the terrestrial analogs for V13, and volcanic tuffs and fissured rocks are those for V14.

Temperature, pressure and dynamics in the lower atmosphere (0–60 km) were measured by all landing and entry probes. T and p vary from $T = 735$ K and $p = 90$ bar near the surface to 260 K and 0.2 bar at 60 km. The temperature lapse rates (gradients) may be compared with the adiabatic lapse rate for the CO_2 (97%) + N_2 (3%) mixture which varies from -11.2 K km^{-1} at 60 km to -8.0 K km^{-1} near the surface. The adiabatic lapse rate corresponds to the static stability of the atmosphere. Significant deviations from static stability were observed at 50–35 km and 22–7 km. Wind speed (measured using the Doppler shift of the radiotransmitter frequency) varies from 70 m s^{-1} at 50 km to 0.5 m s^{-1} near the surface. See also VENUS: ATMOSPHERE.

Abundances of noble gases and isotope ratios were measured by the V11–14 mass spectrometers. The total argon abundance is 100 parts per million (ppm). The ratio of primary isotopes, ^{36}Ar/^{38}Ar, is that on Earth, while the radiogenic isotope ^{40}Ar is depleted by a factor of 270 relative to the Earth's value. The abundance of Ne is 8 ppm, and ^{20}Ne/^{22}Ne $= 12.15 \pm 0.1$, which is between the ratios found on the Earth's (10.1 ± 0.4) and in the solar wind (13.7 ± 0.3). The abundances of Kr and Xe are 35 parts per billion (ppb) and less than 20 ppb, respectively. The isotope ratios for C and O are equal to the Earth's ratios. All these values are important for the origin and evolution of the atmosphere.

Figure 1. Panoramas of the surface of Venus observed from V9 and V10. Each panorama is $180^\circ \times 40^\circ$.

The *chemical composition of the atmosphere* was studied by the V12–14 gas chromatographs: $N_2 \approx 3\%$ and Ar = 100 ppm (both were also measured by the mass spectrometers), $SO_2 = 130 \pm 35$ ppm, CO varies from 30 ppm at 36 km to 17 ppm at 12 km. Detections of some other gases are disputable.

Strong CO_2 and H_2O bands observed at various heights with the V11–14 spectrophotometers resulted in an estimate of the full water abundance of 1 g cm^{-2} above the surface (first done at V11). The absorption at 0.37 μm observed with V14 below 58 km is due to SO_2, which varies from 50 ppm at 50 km to 10 ppm at 57 km.

Observations with the V15 Fourier spectrometer resulted in H_2O abundances of 5–15 ppm at 60 ± 3 km. SO_2 abundances at 70 km were equal to 20–40 ppb at the low and middle latitudes, 1–10 ppb in the polar collar, and 100–1000 ppb near the north pole.

Structure of clouds and aerosols. Illumination. Analysis of the solar radiation scattered in the atmosphere and measured by the photometers and spectrophotometers onboard the V8–14 landing probes established three main layers within the cloud deck structure and the lower cloud boundary at 48 km (near 35 km at V8 and Vega 1 and 2). Optical depths of the layers were derived at each landing sites. The V14 near-UV (0.32–0.39 μm) photometer established two absorption layers, above 60 km and below 58 km. 90% of the solar near-UV energy is absorbed above 60 km and supports strong winds in the upper cloud level. A few per cent of the solar flux reaches the surface.

A nephelometer is an instrument that illuminates a volume of atmospheric medium by a narrow beam and measures the scattered radiation at fixed angles. Four-angle nephelometers were used onboard V9 and 10 and one-angle (backscattering) nephelometers on V11, 13 and 14. They also established the three-layer structure of the main cloud deck and determined aerosol properties in those layers.

The *chemical composition of clouds* was measured by the V12 and 14 x-ray fluorescence spectrometers, which determined the presence of S, Cl and Fe, with the Fe/Cl ratio corresponding to $FeCl_3$. Later, on Vega 1 and 2, this method was used to measure the abundances of S, Cl and P. Gas chromatographic and mass spectrometric analyses of aerosol pyrolysis products (Vega 1 and 2) revealed sulfuric acid and sulfur aerosols with the mass ratio 1:0.1. $FeCl_3$ is probably present as very small (0.3 μm) particles and constitutes 1% of the total aerosol mass. These particles may serve as condensation centers for sulfuric acid and explain the near-UV absorption. The Vega data favor P as phosphoric acid H_3PO_4 at locations where the lower cloud boundary extends to 35 km. The observed excess of Cl may indicate $AlCl_3$.

Lightning. Strong and frequent electromagnetic pulses at 10–100 kHz observed at V11 to 14 favor lightning on Venus. The Pioneer Venus electromagnetic observations also support lightning. However, of three sets of observations in the visible (V9, 10, and Pioneer Venus orbiters, Vega 1 and 2 balloons), there was only one case for suspecting a thunderstorm. Overall, the problem is uncertain.

Properties of clouds and the atmosphere near the upper cloud boundary (68 km) were studied by the near-UV camera, visible spectrometer, photopolarimeter, near-IR spectrometer and IR radiometer onboard the V9 and 10 orbiters, and Fourier spectrometer (FS) on V15.

FS covered the range 5–40 μm with a spectral resolving power $\lambda/\delta\lambda \approx 200$. 1500 spectra obtained mostly in the northern hemisphere showed sulfuric acid as a main cloud species at all latitudes. The cloud deck is homogeneous with a smooth decrease in particle density at latitudes $< 50^\circ$, and is horizontally variable with a steep vertical decrease at the polar and subpolar regions.

Limb observations of haze above the clouds by the V9 and 10 visible spectrometers resulted in vertical profiles of the haze particle size, their number density and eddy diffusion at 70–100 km.

Pressure, temperature and dynamics in the middle atmosphere were studied by three methods: (i) accelerometers on the entry and landing probes, (ii) dual-frequency radio

occultations from the V9, 10, 15 and 16 orbiters, and (iii) FS spectra of the CO_2 band at 15 μm.

50 and 90 p–T profiles in the range 40–90 km were observed with radio occultations from V9, 10 and 15, 16, respectively, to study the thermal balance, day–night variations and latitudinal behavior with a special emphasis on the polar and collar regions. Temperature profiles deduced from the FS spectra are different at low and high latitudes and depend also on local time. Wind velocities ($\approx$ 100 m s^{-1} at 70 km) estimated from the temperature profiles vary with local time, showing the half-day period typical of the atmospheric tides.

Airglow. Observations with the high-sensitive visible spectrometers (V9 and 10 orbiters) solved the three-centuries-old problem of the Venus ashen light (nonzero brightness of the night side) and revealed spectra of the nightglow. Laboratory simulations of these spectra helped to identify four O_2 band systems. Their intensities, vertical profiles and variations with local time were obtained. These emissions originate near $h = 100$ km in the reaction $O + O + CO_2 \rightarrow O_2^* + CO_2$ with subsequent quenching and excitation trasnfer.

Dayglow emissions of H, O, He and O^+ were observed with the V9 and 10 airglow photometers and V11 and 12 spectrometers. The densities of these species and the temperature of the upper atmosphere were obtained from the observations.

Profiles of electron density in the ionosphere were measured using dual-frequency radio occultations from the V9, 10, 15 and 16 orbiters. About 100 profiles were used to study variations of the density maximum and its height, the scale height above the maximum, and the ionopause height with solar zenith angle, solar activity and other geophysical parameters. The nightside ionosphere is especially variable and often shows a two-peak structure.

The *magnetosphere and interaction with the solar wind* were studied by two plasma spectrometers and a magnetometer onboard the V9 and 10 orbiters. The shape and location of the bow shock indicated that the solar wind is diverted almost completely by a magnetic barrier. Charge exchange between the solar wind protons and atmospheric hot oxygen atoms and their photoionization add mass to the solar wind. This mass loading was observed in the boundary layer of the solar wind flow around the planet and plays a crucial role in the formation of the magnetosphere. The planetary ion outflow on the nightside forms the distinct plasma tail. Its polarity is controlled by the local direction of the interplanetary magnetic field, thus confirming the induced nature of the Venus magnetosphere. Both plasma flow from the dayside and electron precipitations on the nightside support the nightside ionosphere (see also VENUS: INTERACTION WITH SOLAR WIND).

Venus

Venus is the second planet from the Sun. It orbits the Sun at 0.72 times the Earth's distance, or 108.2 million km. Because of its location relative to the Earth, Venus is always seen close to the Sun, at less than 48° angular distance from it. The planet appears either as a morning 'star' or as an evening 'star'. Actually, as in the case of Mercury, for a long time it was thought that there were two different bodies (the ancient names for Venus were Eosphorus and Hesperus), until the Greek astronomers realized that there was only one body. The distance of Venus to the Earth varies from 41 million km to 257 million km. As seen from the Earth, Venus's apparent diameter varies from 10 to 64.5 arcsec. However, we see the full disk illuminated by the Sun only at Superior conjunction. The planet has phases, like the Moon (figure 1). They were first seen by Galileo in 1610. Venus is the brightest object in the sky, after the Sun and the Moon, but the planet's brightness is very variable. Venus is the brightest between maximum elongation and inferior conjunction. At inferior conjunction, which happens about every 19 months, when Venus's size is the largest, the disk is completely dark at visible wavelengths. The brightness of Venus is due not only to its close proximity to the Sun (Venus receives twice more solar light as the Earth) and to the Earth but also to the high reflecting power of the clouds that reflect 75% of the solar light.

The rotation of Venus is nearly synchronous. Indeed, the period of rotation of Venus around the Sun is 224.7 days, while the planet's rotational period is 243 days (Earth days), which is extremely slow, and in the retrograde direction (i.e. opposite to the direction of the movement of the rotation of the planet around the Sun). Because of the combined effects of the slow retrograde rotation of Venus and of its orbital motion around the sun, the solar day (time between two sunrises) on Venus corresponds to 117 Earth days. The eccentricity of the orbit and the inclination of the planetary rotation axis are both very small. Therefore no major seasonal changes are expected. In fact, Venus is the planet with the most circular orbit. It is also the most Earth-like of the terrestrial planets in terms of size and bulk properties. The planetary radius at the equator is 6051.5 km, which corresponds to 95% of the Earth's radius (6378 km). Furthermore, Venus's mean density (5.24 g cm^{-3}) and surface gravity (8.6 m s^{-2}) are comparable with those of the Earth (5.97 g cm^{-3} and 9.78 m s^{-2}, respectively). However, now that we know Venus better, we find many more differences from the Earth than was believed only 50 yr ago. In particular, Venus has a very high surface temperature of 740 K (hot enough to melt lead) and a very dense atmosphere (93 times that on Earth). The main atmospheric constituent is carbon dioxide, instead of nitrogen for the Earth. The clouds are made of sulfuric acid and not pure water as on Earth. Besides, the surface of Venus is essentially of volcanic origin and does not present evidence for lateral plate tectonics in recent history. Furthermore, Venus has no intrinsic magnetic field. In addition, Venus does not possess any satellites.

Earth-based investigations

Until the first successful space mission to Venus in 1962, all that was known about Venus came from Earth-based investigations. In 1761, M V Lomonosov, who observed a transit of Venus accross the Sun in an attempt to measure the distance from the Earth to the Sun, was the first to detect a halo around Venus that he interpreted as being due to the presence of an atmosphere. Spots or markings on the planet had been seen since about 1666. Around 1930, ultraviolet measurements detected the Y-shaped features of the upper clouds. Studies of these markings established in 1966 that the atmosphere was rotating in about 5 days at the cloud tops. These features appear much better in the ultraviolet than in the visible. The first identification of an atmospheric constituent was that of CO_2 in 1932 by spectroscopy at 8000 Å. Later on, H_2O was detected from the ground, but also from balloons and aircraft, in visible spectra of the planet and in very variable amounts. Infrared spectroscopy from Earth around 1967 led to the detections of CO, HCl and HF in small amounts above the clouds. Ultraviolet measurements allowed the detection of SO_2 in 1979. The cloud composition remained unknown for a long time. It was believed that the clouds were made of water, as on Earth. It is only around 1974, through the analysis of the polarization of Venus's radiation, that a value for the refractive index of the particles was obtained, $n = 1.45$, and it was then correctly inferred that the cloud particles were in fact droplets of concentrated sulfuric acid (H_2SO_4). This was confirmed later on by space missions, which provided much more information about the clouds. However, it is interesting to note that an explanation for the ultraviolet markings in the upper clouds is still lacking, although it is suspected that they are related to sulfur chemistry.

Measurements of the radio emission of the planet at 3.15 cm in the late 1950s seemed to indicate that the temperature at the surface of Venus was much higher than that on Earth. As it was believed at that time that Earth and Venus were very similar planets, this came as a big surprise, and a confirmation was needed. This was one of the goals of the first American spacecraft that went to Venus in 1962.

Concerning the surface itself, it is only by radar measurements that are not stopped by clouds that information on the surface could be gained. Information on the rotation of the planet as a solid body came only with the first radar studies of Venus with the Goldstone radio antenna around 1964–9 that allowed the direction and rate of rotation of the solid planet to be obtained. The extremely slow rotation thus inferred, and the fact that Venus was rotating in the retrograde direction were other significant surprises. It was also found at that time that the rotation axis is nearly perpendicular to the ecliptic. Radar observations from Goldstone, California, and Arecibo, Puerto Rico, at 12.6 cm (S-band), around Venus's inferior

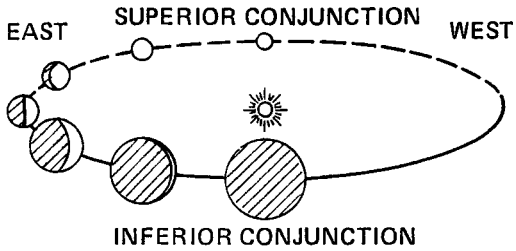

Figure 1. A schematic view of Venus as observed from Earth at various phases. Venus is largest at inferior conjunction, but then it is very dark. At superior conjunction, Venus is smallest but completely illuminated by the Sun. Venus is brightest around east and west elongations. (From Colin L 1983 *Venus* ed D M Hunten, L Colin, T M Donahue and V I Moroz (Tucson, AZ: University of Arizona Press) p 21.)

conjunction, provided the first radar images of portions of the surface at 5–20 km resolution.

The studies of the atmosphere made nowadays by Earth-based telescopes cover all wavelength ranges from the ultraviolet to the radio range. Earth-orbiting ultraviolet satellites as well as sounding rockets are also used regularly to probe the upper atmosphere of the planet.

As the planet is covered by thick cloud layers, the part of the atmosphere below the clouds is difficult to probe by Earth-based observations. For many years, information on the deep atmosphere came essentially from space probes that went into the atmosphere or from occultations of spacecraft by the atmosphere of the planet during a space mission. However, in 1984, it was discovered that the night-side of Venus emits near-infrared radiation coming from deep atmospheric layers below the main clouds. This property has since been used to probe these deep layers using Earth-based telescopes. It led to measurements of sulfur compounds (SO_2, OCS), CO, H_2O and halides (HCl, HF), below the clouds.

Radio measurements that are made today concern mostly the millimeter range, and they pertain to the upper atmosphere of the planet. They provide information on minor species such as CO and H_2O and on the temperature profile in the upper atmosphere. They allow the variations with the time of the day to be studied. For instance, larger concentrations of CO have been found on the night-side than on the day-side. Also, Doppler shifts of the CO lines have been used to measure wind speeds. Long-term variations in CO have also been observed by this method.

Space missions

Space exploration of Venus started in 1962. Since then, there have been many spacecraft explorations with fly-bys and orbiting spacecraft. The most favorable periods for launch occur at times of inferior conjunction, when Venus is closest to the Earth, which happens about every 19 months. Venus is the planet that has been the most explored by space missions.

The first fly-by was that of the American Mariner 2 spacecraft, in 1962, which carried a microwave radiometer to check whether the surface temperature was high. Then, another American spacecraft, Mariner 5, that went to Venus in 1967, confirmed that the surface pressure was very high, about 90 atm. Mariner 10 on its way to Mercury explored Venus in 1974 (see MARINER MISSIONS). The Soviets began exploration of Venus in 1967 with Venera 4 (first successful launch) which carried an atmospheric probe. The first successful landing on Venus was achieved by Venera 7 in 1970 (another Soviet spacecraft), and the first photographs of the surface were obtained by the Venera 9 and 10 Soviet spacecraft in 1975 (see VENERA MISSIONS). Venera 8, 9 and 10 lander capsules carried gamma-ray spectrometers, which allowed the first geochemical measurements to be made. The amounts of radioactive elements U (uranium), Th (thorium) and K (potassium) were determined.

Then, in 1978, came the American Pioneer Venus 1 and 2 missions, with an orbiter on Pioneer Venus 1 and entry probes on Pioneer Venus 2. Pioneer Venus orbiter penetrated the upper atmosphere and made mass spectrometer measurements. Four probes reached the surface. The orbiter part of the mission lasted from December 1978 to October 1992. Topographic maps were obtained by the radar altimeter on Pioneer Venus 1 in 1978 with a resolution of about 50 km in horizontal extent and about 200 m in altitude (see PIONEER VENUS MISSION). The Venera 11 and 12 spacecraft, which carried descent landers, were also sent to Venus by the Soviet Union in 1978. Altogether, in December 1978, ten separate spacecraft visited Venus.

The Soviet exploration continued with other Venera missions (up to Venera 16) and with the Vega 1 and 2 spacecraft that were initially designed for an exploration of Venus but were sent to comet Halley as well as to Venus (see VEGA SPACE MISSION). The Venera 13 and 14 probes, which landed on Venus in 1982, and the Vega 2 probe, which dropped a landing module in June 1985, carried an instrument that was able to measure the x-ray fluorescence of soil samples introduced into a vacuum chamber. Venera 13 and 14 obtained some more images of the surface of Venus, and the Venera 15 and 16 probes provided radar mapping at a resolution of 1–2 km of the northern 25% of the surface of Venus close to the north pole, starting in 1983.

Another major step in the exploration of Venus was achieved by the American Magellan Radar Mapping spacecraft that was launched from the space shuttle Atlantis in 1989. Between 1990 and 1992, it mapped 98% of the surface at resolutions between 120 and 300 m. It also provided altimetric, radiometric and gravity data. The final orbit occurred on October 1994. The radar maps are spectacular. The American spacecraft, Galileo, designed to explore the planet Jupiter, accomplished a fly-by of Venus in February 1990. It has allowed us, in particular, to study the deep clouds of Venus from near-infrared imaging of the night-side.

The atmosphere

Composition and temperature

Our current knowledge of the composition of the atmosphere of Venus comes from a number of *in situ* analyses with infrared and ultraviolet spectrometers, mass spectrometers and gas chromatographs on space probes that went into the atmosphere of the planet. It is also the result of spectroscopy obtained with Earth-based telescopes, airplanes, rockets and satellites. Venus has a very dense atmosphere, with CO_2 as the major constituent (mixing ratio: 0.965), instead of N_2 as on Earth. Minor components are nitrogen (N_2), water vapor (H_2O), sulfur dioxide (SO_2), sulfur monoxide (SO), carbon monoxide (CO), carbonyl sulfide (COS), sulfuric acid (H_2SO_4), oxygen (O_2), hydrogen chloride (HCl), hydrogen fluoride (HF), argon (Ar), neon (Ne) and krypton (Kr) (see VENUS: ATMOSPHERE). The atmospheric surface pressure is 95 bar, or 95 times that at the surface of the Earth. The temperature at the surface is very high: 740 K.

One of the striking characteristics of Venus is its dryness. At the high surface temperature of Venus, water could not currently exist in the liquid state at the surface. However, even in the atmosphere, only very small amounts of H_2O vapor are found. The deuterium-to-hydrogen ratio is very high (about 150 times that on Earth). In contrast, isotopic ratios of C and O are the same on Venus and Earth.

Concerning the nonradiogenic noble gases ^{20}Ne, ^{36}Ar and Kr, ^{20}Ne is about 20 times more abundant on Venus than on Earth, ^{36}Ar about 70 times more abundant and Kr only 3 times more abundant. Radiogenic argon (^{40}Ar) is about 4 times less abundant on Venus than on Earth.

The high average surface temperature is somewhat surprising. Indeed, in spite of the close proximity of Venus to the Sun, because of the high reflecting power of the clouds, only about 25% of the solar flux penetrates into the atmosphere. However, the high surface temperature can be explained by a very efficient greenhouse effect as the atmosphere of Venus contains gases that are strong infrared absorbers (CO_2, SO_2, H_2O, OCS) and clouds that trap the thermal radiation emitted by the deep atmosphere. This causes an increase in the surface temperature of nearly 500 K (compared with the expected temperature without an atmosphere).

The measurements of temperature in the atmosphere come from infrared radiometry and radio occultations. Spacecraft radio-occultation measurements indicate that the temperature decreases from 740 K at the surface to about 240 K at the cloud tops. Temperatures below 35–50 km approximately follow an adiabat. This indicates that the temperature structure below the clouds is controlled essentially by atmospheric dynamics (convection). Diurnal and latitudinal variations are very small below the clouds.

Above the clouds, in the region called the mesosphere, temperature measurements obtained from Pioneer Venus around 15 μm have provided maps covering the 60–105 km vertical range. The temperature (averaged over time) varies from 170 to 330 K. These maps indicate that, at these altitudes, the polar regions are up to 20 K warmer than the equator, which is very surprising.

At still higher altitudes, in the thermosphere, the temperature in the day-side is around 300 K, and therefore much colder than on Earth (where it is 1000–2000 K). Heating in this part of the atmosphere is caused mainly by the absorption of ultraviolet photons from the Sun. The difference in temperature with respect to the Earth is due to the greater abundance of CO_2 which is very efficient at radiating heat to space. The temperature varies spectacularly from day to night. At night, it can be as cold as 100 K. The long duration of the days on Venus and the cooling effect of CO_2 on the night-side probably combine to produce this strong contrast in temperature.

The homopause is the region of the atmosphere above which the gases are no longer uniformly mixed (gases of different mass have different scale heights). On Venus, this occurs at around 130–145 km altitude. What is found is a surprisingly low concentration of the dissociation products of CO_2—O and CO—above the homopause. These products must be quickly removed and transported to lower altitudes where they recombine (maybe through a catalytic cycle that involves chlorine, which is about 1000 times more abundant on Venus than on Earth).

Still higher up, Venus has an ionosphere, which was first detected by the radio-occultation experiment on Mariner 5 in 1967 and has been studied in more detail by an ion-mass spectrometer that went to the ionosphere and by remote-sensing observations with other instruments on the Pioneer Venus orbiter. The day-side ionosphere peaks near 140 km and stops at about 500 km. It is produced primarily by solar extreme ultraviolet radiation. The most abundant positive ions are O_2^+, O^+ and CO_2^+. O_2^+ (and not CO_2^+) is the dominant ion up to about 190 km because of the rapid reaction rate of CO_2 + O. Higher up, O^+ dominates. Quite surprisingly, the night-side ionosphere can sometimes be rather significant. This happens during periods of solar maximum when the day-side ionosphere is so dense and extensive that the solar wind cannot penetrate the planet's environment. A large flux of O^+ ions then goes to the night-side of the planet and creates a significant night-side ionosphere (the long duration of the nights prevents the ions from recombining). At solar minimum, the day-side ionosphere is much less extensive, and the flow of ions to the night-side not as strong (see VENUS: INTERACTION WITH SOLAR WIND).

Clouds

Although the upper part of the cloud layers can be observed and monitored from the Earth, the vertical structure of the clouds can be studied only during space missions. Probes and the Vega 1 balloons have gone through the cloud layers, and the Galileo spacecraft has imaged the clouds on the night-side of the planet around 40–50 km altitude during its fly-by of Venus.

Clouds cover Venus globally in generally three layers between 48 and 68 km. At some times and at some

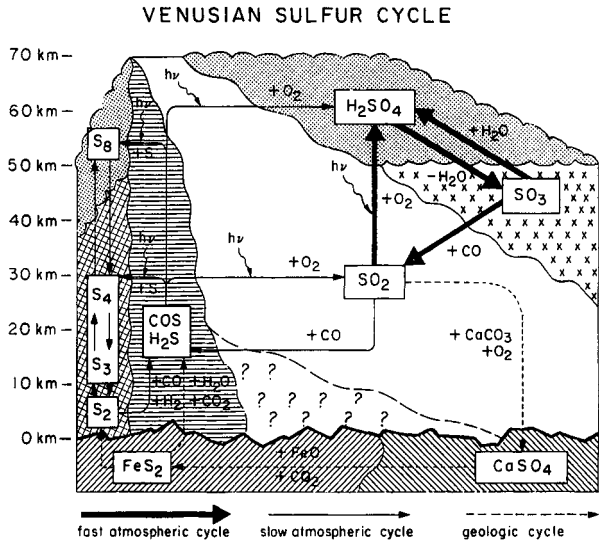

Figure 2. A possible model for the Venusian sulfur cycle (from Lewis J S and Prinn R G 1984 *Planets and their Atmospheres: Origin and Evolution* (New York: Academic).

locations, the lower two layers may combine. However, the variability in structure is much less important than in the Earth's clouds. Hazes are present above and below the clouds. The total cloud optical depth has been estimated to be between 25 and 35. Their total mass is relatively small; the Venus clouds are more like the hazes on Earth. The droplets are about 2 μm in size, but the particle size distributions differ from layer to layer.

The clouds are made mostly of concentrated sulfuric acid, with about 75% by weight sulfuric acid and 25% water vapor. They resemble terrestrial acid rain (caused by pollution). This composition is probably the result of photochemical production of SO_3 from SO_2. H_2O and SO_3 then react to make H_2SO_4 (figure 2). H_2SO_4 is thermally decomposed into SO_3 and H_2O in the lower atmosphere. Chemical reactions with the surface should be removing sulfur quickly from the atmosphere, maybe through the formation of anhydrite ($CaSO_4$). Some sulfur must go back into the atmosphere from the decomposition of sulfur compounds present in the crust, such as pyrite (FeS_2). To explain the presence of permanent cloud layers of sulfuric acid on Venus, a source of sulfur (continuous or episodic) is needed, and it is postulated that surface volcanism plays an essential role in the release of sulfur gases from the crust (see also CLOUDS IN PLANETARY ATMOSPHERES).

Atmospheric circulation

The atmospheric circulation of Venus is very different from that on Earth (see EARTH'S ATMOSPHERE). This is not surprising given the different rotation rates, the different atmospheric composition and structure, and the lack of seasons. Furthermore, on Venus, solar light is mainly deposited within and above the upper cloud layer which is always present, whereas on Earth it is mostly absorbed at the surface.

What we know about the global circulation in the atmosphere of Venus comes from various sources of information. Direct sources are cloud-feature tracking and the radio tracking of descending probes (Doppler tracking of Veneras 8, 9, 10 and 12 and interferometric tracking of the Pioneer Venus probes) and of balloons that went into the atmosphere (Vega mission). Doppler-shifted emission lines from atmospheric gases (such as CO_2 and CO) also provide direct measurements of wind speeds. Spatial variations in gaseous abundances are also used as tracers of the global circulation. In a more indirect way, theoretical analyses of planet-wide variations in temperature at a given pressure, obtained by radio occultations and IR radiometry, have been used. However, winds can be determined in this manner only if the atmosphere is in cyclostrophic balance, a condition which, on Venus, occurs in the non-equatorial regions below 60 km altitude.

As we have seen, Venus rotates extremely slowly, in 243 days, whereas the atmosphere at the cloud levels (around 60 km altitude) rotates in 4–5 days, which corresponds to wind speeds of 100 m s^{-1}, in the same retrograde direction as the planet. This zonal (along a line of constant latitude) superrotation of the entire atmosphere of Venus from about 10 km up to about 100 km, which is so different from what is found on Earth, is the main mode of circulation of the atmosphere.

The zonal winds are not constant with altitude, however. They decrease regularly from a speed of 100 m s^{-1} at the cloud tops to values close to 1 m s^{-1} near the surface. However, there exist some layers of relatively constant wind speeds that alternate with regions of large increase in velocity. Differences in zonal wind speeds with time of the day also exist.

Above the clouds, zonal winds generally decrease with altitude up to about 100 km, where they reach very small values. At still higher altitudes, a very different circulation regime exists. The global circulation is there dominated by a strong flow from the day-side hemisphere to the night-side hemisphere (subsolar to antisolar circulation). Peak velocities reach approximately 250 m s^{-1} across the terminator. This circulation, which is also different from that existing on Earth, is a consequence of the high temperature contrasts between the day-side and the night-side above 150 km. With only a strong subsolar-to-antisolar flow, one would expect upwelling centered on the subsolar point and subsidence centered on the antisolar point, with a return flow around 70–90 km altitude. However, subsidence does not occur at midnight but, instead, at around 2–3 a.m. local time. This asymmetry may be due to the superposition of the subsolar-to-antisolar flow and of some zonal retrograde winds (these two flows add across the evening terminator, but go in opposite directions at the morning terminator).

There is, in addition, a slow meridional (in the equator-to-pole direction) circulation that may consist of Hadley cells, as on Earth. Cloud-tracked winds from

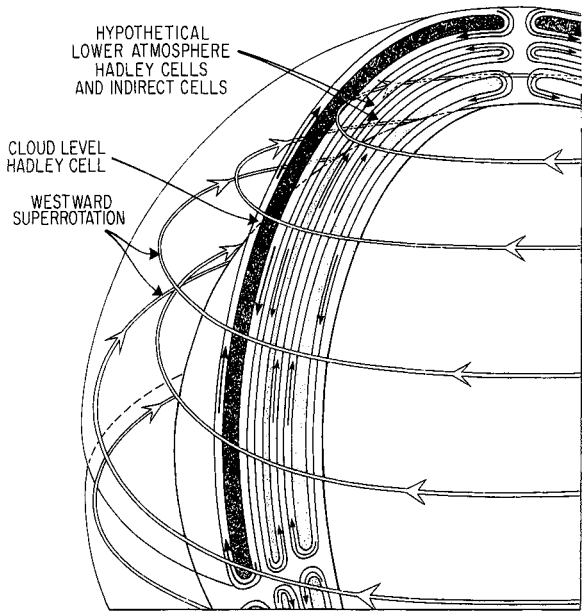

Figure 3. A possible model for the general circulation of the Venusian atmosphere (from Schubert G 1983 *Venus* ed D M Hunten, L Colin, T M Donahue and V I Moroz (Tucson, AZ: University of Arizona Press) p 730.)

Pioneer Venus and Mariner 10 have shown equator-to-pole velocities of about 5 m s^{-1} in each hemisphere. However, the interferometric tracking of the Pioneer Venus probes has revealed a complex altitude variation, with changes in magnitude and in direction. Interpretations of these observations and theoretical considerations suggest that the Pioneer Venus probes went through several vertically layered large meridional cells that each extend from the equator to high latitudes. There may be three different cells: a Hadley cell near the surface, a weak indirect cell in the stable layer below the clouds (between 30 and 50 km) and a Hadley cell at the cloud level (that may be 'thermally indirect') (figure 3).

There are many indications of wave motions on different scales in the atmosphere of Venus. In particular, the relative stability of the large-scale dark markings in the ultraviolet photographs may be due to planetary-scale waves drifting slowly with respect to the atmospheric superrotation. The thermal tides that follow the motion of the Sun in Venus's sky (the Sun rises in the west and sets in the east) may also play an important role. There is also evidence for small-scale turbulence. One of the main problems in Venus's global circulation is to explain the existence and maintenance of the superrotation. The eddies that have been observed in the lower atmosphere may, in combination with the mean meridional circulation and the planetary-scale waves, help in providing the upward transport of angular momentum required to explain Venus superrotation.

Origin and evolution

Although giant planets have retained most of their primitive atmosphere, this is not the case for the terrestrial planets Venus, the Earth and Mars that have lost their primitive atmosphere, probably through massive escape, and have acquired a secondary atmosphere. A large part is made of gases outgassed from the interior which is heated during planetary formation by contraction and by decay of natural radioactive elements. During periods of large-scale volcanism, CO_2, SO_2, H_2O and other volatiles are injected into the atmospheres. An extra component comes from cometary and meteoritic impacts (for the Earth, biological processes also play a role). Gases can be removed by atmospheric escape (solar wind interaction), interaction with the surface or major impacts. See also PLANETARY ATMOSPHERES.

As Venus and Earth were formed in approximately the same region of the solar nebula, they may have had the same global composition. There are some indication that this may be the case. Indeed, the total estimated oxidized carbon inventories on Venus and Earth are comparable, although on Earth the carbon is mainly present in carbonate rocks at the surface of the planet and in the oceans while, on Venus, it is mainly present in the atmosphere, where it can accumulate because of the absence of liquid water. Nitrogen inventories on Earth and Venus are also comparable.

The underabundance of radiogenic argon ^{40}Ar (produced by the decay of ^{40}K—potassium) could be due to different outgassing rates and/or duration on Venus and on Earth. If it is due essentially to a shorter duration of outgassing on Venus than on Earth, then the measurement would indicate that most of Venus's outgassing happened during the first billion years.

The high values of the nonradiogenic noble gases ^{20}Ne, ^{36}Ar and Kr on Venus compared with Earth have not yet found a completely satisfactory explanation. The postulated early episode of massive supersonic escape of the early hydrogen-rich atmospheres by enhanced extreme ultraviolet radiation from the young Sun would probably have carried along the noble gases on both Venus and the Earth, in spite of their high molecular weight. The only major difference in the evolution of the two planets may come from the giant impact with a planetesimal that must have occurred on Earth (but not on Venus) to explain the Moon's formation. This would have produced another major erosion of the Earth's atmosphere, including the noble gases, and, according to some scientists, it could be the main reason for smaller abundances of noble gases on Earth than on Venus (except for Xe, which may be a particular case because of its higher molecular weight). The current endowment in these noble gases for the Earth would come essentially from subsequent periods of outgassing from the interior, with, maybe, some additional contribution of less destructive and more recent cometary or meteoritic impacts that could enrich the atmosphere in noble gases. More measurements of noble gas abundances

on Venus, as well as measurements in comets, are needed to enable the further development of these hypotheses.

Venus's atmosphere currently contains about 100 000 times less water than is found in the oceans and atmosphere of the Earth. Venus could originally have had the same amount of water as the Earth. A significant loss of water could have occurred on Venus, but not on Earth, because of a runaway greenhouse effect due to the much higher temperatures of Venus that would have vaporized the water. The water molecules dissociate in the upper atmosphere, and hydrogen then escapes. After a period of massive escape, it has been computed that fractionation would start (the heavier deuterium D does not escape as easily as the lighter H) after the amount of water has been reduced to the equivalent of a layer of water a few meters thick covering the surface of Venus. The very high value of the D/H ratio measured on Venus could therefore indicate that much larger amounts of water were present in the past, with, maybe, the possibility that OCEANS once existed on the planet. However, such calculations are not simple, as it is hard to track the amount of water present at a given time. Indeed, during the more recent past, significant ejections of water could have been produced by a major volcanic episode or by a massive outgassing event. Furthermore, cometary impacts continually replenish the atmosphere with relatively weakly deuterated water.

Surface and interior of Venus

Little was known about the surface until the 1970s. After the first observations by Earth-based Goldstone and Arecibo radar mapping in the 1960s, global-scale radar mappings of large parts of the surface were carried out by Pioneer Venus in 1978 and Venera 15 and 16 in 1983. This was then followed by the US Magellan mission in 1990–4 that has provided radar images, altimetric and radiometric data at a remarkable spatial resolution of 120–300 m for 98% of the surface of Venus.

Main characteristics of the surface

The radar altimetric data indicate that more than 90% of the surface has an elevation between −1 and +2.5 km, compared with Venus's reference mean radius of 6051.8 km. The surface is dominated by plains. One can distinguish the lowland plains (or planitiae), such as the Atalanta Planitia, that have elevations between 1 and 2 km below the mean Venusian radius and that cover about 27% of the surface, and the upland or rolling plains that constitute 65% of the surface and have elevations between 0 and 2 km above the mean surface radius. The rest (about 8% of the surface) is made of highlands with 2–12 km elevation.

The lowland plains are generally very smooth (dark at radar wavelengths), whereas the upland or rolling plains are a little more rough and possess many small-scale landforms such as scarps, ridges, troughs, hills, channels, ... The plains are interrupted by the large-scale landforms at higher elevations called highlands (see VENUS: SURFACE).

The highlands are dominated by two continent-size features: APHRODITE TERRA and ISHTAR TERRA (figure 4). The largest one, Aphrodite Terra (about 10 000 km across), is larger than Africa in surface area. It lies mostly in the southern hemisphere, close to the equator, at 1–5 km elevation. Ishtar Terra, about 5600 km across (about the size of Australia), and located in the northern hemisphere, possesses the highest mountain belts on the planet, including Maxwell Montes which is up to about 12 km high. Following V L Hansen and colleagues, the highlands can be subdivided into three groups: the volcanic rises, the crustal plateaux and Ishtar Terra. The volcanic rises are more than 1000 km across, they rise 1–2.5 km above the surrounding plains and they have gentle slopes. They include the Atla, Beta, Bell, Dione, Imdr and Themis Regiones. The most prominent volcanoes on Venus and numerous coronae (which are circular to elliptical features with tectonic annuli unique to Venus) are found there. The volcanic rises are mostly located in equatorial regions of Venus. The crustal plateaux such as Ovda and Thetis in Aphrodite Terra, or the Alpha, Phoebe or Tellus Regiones are 1000–3000 km across; they have steep slopes and reach elevations of 2–4 km above the surrounding plains. They contain regions of very rough, highly deformed terrain called tesserae, and some volcanic features, as well as many other structures such as ridges, fractures and grabens. Ishtar Terra has unique characteristics; it is an irregular platform with a complex topographic profile that includes a high interior plateau, Lakshmi Planum, with mountain belts in its periphery, and surrounding high tesserae. In addition, its tesserae are different from the ones found elsewhere. They have more coherent structures.

Thousands of volcanoes have been identified on Venus, from kilometer-size vents to broad shields hundreds of km across. Volcanoes and other volcanic features are found everywhere, but they are less abundant in the tesserae regions and more abundant in the Beta–Atla–Themis region which covers about 20% of the planet. So far, 167 volcanoes more than 100 km across have been found. Examples are Maat Mons in Atla Regio (figure 5) and Theia Mons in Beta Regio, which have diameters in the range 100–200 km and rise to 1–9 km above the mean planetary radius. These volcanoes are surrounded by radar-bright (rough) ejecta with circular or elliptical shapes that sometimes form kinds of festoons. About 300 intermediate-size volcanoes have been found (20–100 km in diameter), including several 'pancake domes' that are steep-sided, circular, flat-top features. The smallest volcanoes are mostly found in groups called shield fields.

There are about 1000 impact CRATERS on Venus, which is not much compared with what is found on Mars or the Moon. The largest crater, Mead, has a diameter of 270 km, and the smallest ones have diameters of about 1.5 km. The absence of small craters and the fact that craters on Venus seem to come in groups are probably due to the presence of a dense atmosphere around the planet that has broken the large meteroids and completely burnt

smaller ones. Higher crater densities are usually found in the plains. Most craters are pristine. The low number of craters, their distribution and their shapes suggest that the surface of Venus cannot be older than 500–800 million years on average.

Information on the surface composition comes from *in situ* data and from radar data. The geochemical data from the Venera 9, 10, 13 and Vega 1 and 2 landers imply a predominantly basaltic composition, with one site indicating possibly more alkalinic rocks. Venera 8 found a more granitic composition for the soil. Radar backscatter is a function of both roughness and the bulk properties of the target material. The radar properties of the lowland plains indicate surface dielectric constants of 3–8, which corresponds to low values of the dielectric constants of basalts on Earth. Much higher dielectric constants have been found for some regions at high elevation. They can be explained by highly conducting materials such as iron-bearing minerals (pyrite (FeS_2) or iron oxides such as magnetite (Fe_3O_4)) but identification of a specific phase which would exist only in a narrow band of elevation is problematic.

Volcanism and tectonism

Volcanic deposits and volcanic centers are very important characteristics of the surface of Venus. The processes of volcanism have been largely preserved on this planet, which is not the case for Mars and the Earth (see VOLCANISM IN THE SOLAR SYSTEM).

The plains are apparently completely covered by volcanic deposits. Concerning the volcanic centers, one can distinguish two main categories. The first category is characterized by very significant flows that generally come from a vent region during repetitive eruptions. It includes large and intermediate-size volcanic edifices, flow fields and calderas. To explain the formation of centers of repetitive volcanic eruption it is necessary to assume the presence of stable shallow magma reservoirs. The global eruption rates corresponding to the population of large volcanoes have been estimated by L S Crumpler and colleagues to be about 1.7×10^{-2} km^3 yr^{-1} of magma.

The second type concerns regions of the order of 100–200 km in diameter characterized by the presence of many small edifices and by relatively limited associated volumes of lava flows. It includes the groups of small-size edifices that are called shield fields. Some calculations indicate that these shield fields form where magma replenishment rates are about 10^{-4} km^3 yr^{-1} or less, but there is no estimate of the global rate for this category.

Concerning Venus's resurfacing history, it looks as if a substantial decrease in area resurfacing rates from about 4 km^2 yr^{-1} during plain emplacement to about 0.5 km^{2}yr^{-1} over the past 290 million years has occurred. This reduction has probably been accompanied by a change in volcanic style from flood-type volcanism in the plains to more localized development of volcanoes, coronae and rifts.

Concerning the types of lava, some indication comes from the existence and morphology of some of the

channels observed on Venus. The longest of the various classes of channels observed on Venus are called canali. They have remarkably constant width along very long paths, exceeding 500 km and up to 6800 km (Baltis Vallis). They are 1–3 km wide, and their depth seems to be less than 50 m. Highly fluid lavas, that have erupted during sustained, high discharges, seem best to explain many of the channel features, particularly the canali.

Possible candidates for this fluid are native sulfur or, preferably, alkali–carbonatite lavas (very rare on Earth) which would have resulted from the melting of the crust altered by interaction with the CO_2–SO_2–halogen-rich atmosphere. In contrast, the pancake domes and festoon flows correspond to high-viscosity lavas.

Hundreds of coronae are distributed across the surface, most with diameters of less than 300 km, but a few exceed 1000 km in diameter. They are not seen on any other terrestrial planetary body. Many of them are associated with rift zones, forming linear chains thousands of kilometers long. In other places, they occur individually or in clusters in the plains. All coronae have some association with volcanism. Coronae may represent collapsed domes over large magma chambers.

There are numerous other tectonic surface features on Venus that have been formed by compression or by extension: ridges, valleys, mountain belts, ... In tesserae, one finds ridges and grooves that intersect and form very chaotic patterns. They probably reflect a complex deformation history. One also finds rift zones on dome-like features that are linear depressions that probably formed where Venus's lithosphere has ruptured owing to horizontal extension. The most important one is Beta Regio, which presents some analogy with the terrestrial East African Rift.

Geological evolution and the interior of Venus

Studies of impact craters on Venus indicate that about 80% of the history of Venus is not accessible to us. The surface we see is very young. The oldest terrain on Venus is tesserae. They are probably due to intensive tectonic deformation. Other apparently younger tectonic features must have formed during successive episodes of compressional and tensional deformations: fractures, broad ridges, wrinkle ridges. A period during which several stages of extensive volcanism occurred, burying areas of tesserae and forming the plains we see now, probably occurred afterwards.

Similarities in mean density and moment of inertia factor between Earth and Venus could indicate similar bulk compositions and internal structures. Models suggest that the interior of Venus is indeed compositionally similar to the Earth, except for small differences in iron, sulfur and oxygen content. Venus has certainly differentiated. It must have a crust, a mantle and a core. Although the relatively large value of the mean density of Venus strongly suggests that the planet has an iron core, Venus lacks an intrinsic magnetic field that would be strong evidence that at least part of its core exists in the liquid state, as is the case for Earth. Most models predict the radii of the core and mantle to be of the order of 3200 and 2800 km, respectively. Venus probably has a lithosphere, as does the Earth, but gravitational data indicate that it most likely does not have the low-viscosity astenosphere that exists on Earth below the lithosphere.

Most of the sites exhibit compositions similar to basalt, a volcanic rock that is very common on Earth and that constitutes most of the Earth's seafloor. The crust, therefore, probably formed from melting of an upper mantle with an Earth-like composition. Theoretical models constrained by the observed depths of impact craters and the spacings of ridges and rifts imply crustal thicknesses in many parts of Venus of 10–20 km, which is less than the average thickness of the Earth's continental crust (about 40 km) but greater than the thickness of the oceanic crust (about 6 km). Gravitational data indicate that the mean thickness of Venus's crust is 20–50 km. Alternatively, arguments based on mineralogy and high topographic elevations suggest crustal thicknesses in some areas of 100 km or more. Seismic probes are needed to obtain more information on the thickness of the crust.

The depth of the lithosphere is even more uncertain. Some think that Venus's lithosphere may be thicker than Earth's, owing to its lower water content in mantle rocks, thus making its surface geology somewhat less active. Others speak of a lithosphere only about 100 km thick, similar to or thinner than Earth's. They argue that the high temperature of the surface of Venus prevents a thick lithosphere from forming because the rocks are near their melting points.

Based on the identification and study of the different types of volcanic and tectonic features on Venus, and on gravitational data, it appears that there cannot be on Venus a global plate-tectonic activity as on Earth. There is instead evidence for active mantle convection with a recycling that occurs mainly in the vertical direction through regions of upwelling and downwelling. According to some models, volcanic centers must be associated with regions of mantle upwelling. The long-lived plumes (which are narrow regions of hot mantle upwelling) that allow sustained eruptions may be at the origin of the large volcanoes. Short-lived plumes may explain coronae. They may be due to local upwelling currents in Venus's mantle (figure 6).

One must also take into account the fact that the lithosphere may have been thin early in the history of Venus and has thickened with time. This would result in differences in the surface response above mantle upwellings. For instance, as has been suggested by some scientists, crustal plateaux could represent the interaction of ancient deep thermal plumes (or hotspots) with a thinner lithosphere. In contrast, volcanic rises may have formed only in the relatively recent past, after Venus's lithosphere had thickened enough to support them.

The gravitational data and the presence of ridge belts that indicate compressive stress suggest that the plains may correspond to regions of mantle downwelling on a broad scale. Regions of diffuse mantle upwelling would result instead in extension of the lithosphere and formation of coronae and chasmata (the chasmata are arrangements of troughs and scarps).

There is certainly a very complex time evolution. The regions of mantle upwellings and mantle downwellings may change location with time, which could result for instance in formation of coronae and chasmata in plain

regions. In contrast, some early-formed crustal plateaux may have collapsed owing to changes in temperature or to tectonics and could constitute some of the plains we see today.

Venus: Atmosphere

VENUS is the nearest planet to the Earth, both in terms of distance and in overall size and mass (table 1). However, Venus has lost most of its atmospheric and surface water, probably because it is significantly closer to the Sun. As a result of this, much of the carbon dioxide which on the Earth has been processed by the oceans to produce carbonates is still free in the atmosphere on Venus. This in turn means that Venus' atmosphere is very massive by terrestrial standards, with a surface pressure of almost 100 bar and a searingly high surface temperature in excess of 730 K.

The rotational axis of Venus is nearly perpendicular to the ecliptic, and the orbit is nearly circular, so seasonal changes in the climate are probably very small. The Venusian year is 224.7 Earth days, longer than the time for Venus to rotate on its axis, which is 243 Earth days. The solar day, defined as the time for the Sun to go from noon to noon as seen from the surface of Venus, is about 117 Earth days. This very slow rotation of the solid body of Venus is retrograde, i.e. backwards compared with the other planets, a curious state of affairs which is difficult to explain in terms of currently accepted models of the evolution of the SOLAR SYSTEM. The resulting absence of a strong Coriolis force at the surface is likely to be a major factor in determining the structure and dynamics of the atmosphere. Persistent high winds of the order of 100 m s^{-1} are observed near the cloud tops, 50 or 60 km above the surface, where the density of the air is similar to that near the ground on the Earth. It is not known reliably how these are produced.

The surface of Venus is obscured at visible wavelengths by planet-wide cloud cover, the upper layers at least consisting of sulfate aerosol similar to the much thinner layers of volcanic origin found in the terrestrial stratosphere (see VENUS: SURFACE). On Venus, the clouds have a complex layered structure and, although never completely absent, their coverage is very variable. They play an even larger role in the energy balance of the planet than clouds do on Earth, through their contribution to the atmospheric 'GREENHOUSE EFFECT'.

Localized dynamical or 'weather' activity on Venus, as far as is known at present, is dominated by four major phenomena: the cloud-top zonal super-rotation, the ultraviolet markings and associated planetary waves, cumulus dynamics in the deeper layers and the double-vortex structures at the poles. These and other types of activity, such as atmospheric tides, are no doubt linked to each other and to the general circulation, but all remain poorly understood.

Energy balance

At a distance of 108.2 million km, Venus is closer to the Sun than the Earth by a factor of about $2^{\frac{1}{2}}$, and so has about twice the incidence of solar energy. It is also much hotter at the surface, nearly $2\frac{1}{2}$; times more than the terrestrial mean of about 300 K. These facts are not simple to reconcile, however, because the ubiquitous and highly reflective cloud cover on Venus reflects 76% of the incoming solar flux and this results in a *smaller* net solar constant for Venus than for Earth. The high surface temperature must, therefore, be due to 'greenhouse' warming produced by the thick, cloudy atmosphere, possibly augmented by a contribution from the internal heat of the planet.

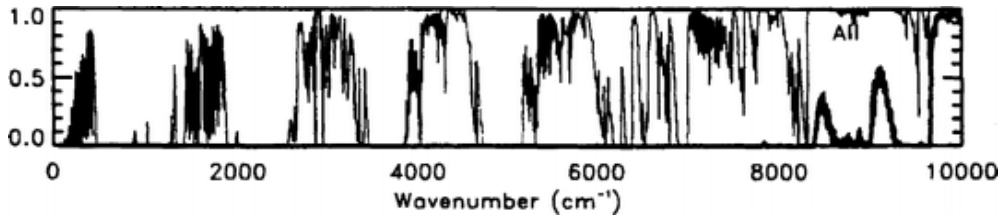

Figure 1. The computed transmission of Venus' atmosphere from the surface to space, showing the spectral gaps to be plugged by cloud opacity in order to maintain the observed 'greenhouse' effect (V Meadows and D Crisp).

It is not simple to prove that the observed atmospheric conditions can in fact generate such a large 'greenhouse' effect. The problem is that the massive amounts of carbon dioxide are very effective at blocking the emission of thermal infrared radiation, but only at those wavelengths where the gas has absorption bands, which are far from covering the entire spectrum. Moderate amounts of water vapor are also required, and even then considerable spectral gaps or 'windows' remain (figure 1). These could be blocked by the clouds, since liquid or solid absorbers present some opacity at every wavelength, the details depending on composition and particle size. The difficulty for early theorists was that using clouds to 'close' the greenhouse also tended to block the incoming sunlight, so that the calculated equilibrium temperature of the surface remained well below that observed.

This problem began to be resolved when it was realized that the clouds are made of sulfuric acid droplets, at least in the higher, most easily measured layers. These have the property of being highly absorbing at thermal infrared wavelengths, while being nearly conservative scatterers in the visible and near-infrared. Thus, the clouds tend to diffuse downwards those of the incoming solar photons that they do not reflect to space, while blocking thermal emission from the lower atmosphere and surface. This explains the result, surprising at the time, that the VENERA landers in the 1970s were able to photograph the surface in natural light. It also means that radiative transfer models, involving weak as well as strong bands of CO_2 and H_2O, plus those of the minor constituents CO, HCl and SO_2, can account for the high surface temperatures by careful incorporation of the scattering and absorbing properties of the clouds.

The total solar energy diffusing through the cloud cover on Venus corresponds to about 17 W cm^{-2} of surface insolation on the average, about 12% of the total absorbed by the planet and the atmosphere. The high opacity of the gaseous atmosphere and cloud at longer wavelengths requires the surface to reach temperatures high enough to melt zinc before the upwelling flex is intense enough, and at shorter wavelengths, so that equilibrium is attained. An airless body with the same ALBEDO and at the same distance from the Sun as Venus would reach equilibrium for a mean surface temperature of only about 230 K. This 500 K greenhouse enhancement of the surface temperature compares with only about 30 K on Earth and 10 K on Mars.

Composition

The primordial atmosphere of Venus which originally formed with the solid body, like those of the other TERRESTRIAL PLANETS, was likely to have been lost in the distant past as the young Sun went through phases of high activity. The present atmosphere would have been produced much later by outgassing from the crust, a process which we are probably observing today as active volcanism, and by the influx of cometary and meteoritic material, which is also still going on. The relative contributions of these distinct sources can, to some extent, be deduced from the data which are gradually being accrued on the composition, and in particular the isotopic ratios, in the contemporary terrestrial planet atmospheres and in comets and meteorites.

COMETS are a rich source of volatile compounds such as carbon dioxide, water vapor, methane and ammonia. If the last of these was the source of the nitrogen now present, and we allow for processes such as the production of argon by the decay of radioactive potassium in the crust, the contemporary atmosphere could all be of external origin. On the other hand, the high abundance of sulfur in Venus' clouds is strongly suggestive of extensive volcanic activity and volcanoes are also prolific sources of carbon dioxide, nitrogen and the other gases required to explain present-day Venus.

Apart from carbon dioxide and water vapor, Venus' atmosphere consists primarily of inert gases, particularly nitrogen and argon (table 2). The amount of water present as gas and bound up with sulfuric acid and other compounds in the clouds is between 10 and 100 000 times less than exists in the oceans and atmosphere of the Earth (see EARTH'S ATMOSPHERE). Thus Venus is overall very dry compared with the Earth while, at the same time, deuterium is about 100 times more abundant on Venus than Earth. This suggests that Venus may have had much more water initially, but that most of it has been lost. Loss takes place by dissociation of the water in the upper atmosphere by solar ultraviolet radiation and the subsequent escape of the hydrogen. Both deuterium and normal hydrogen escape from the atmosphere while there is free water on the surface, but the heavier isotope

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

escapes less efficiently, leading to the observed fractionation.

The loss rate of the water depends strongly on its abundance in the relatively cool middle atmosphere as well as the intensity of the solar ultraviolet flux. Models of the process suggest that Venus could have lost an ocean of present-day terrestrial proportions in only a few hundred million years. The oxygen produced at the same time is too massive to escape at any significant rate, according to Jeans' formula, and must remain on the planet, presumably most of it bound chemically within the crust, mainly as carbonate rocks. As on the Earth, this process would remove atmospheric carbon dioxide efficiently as long as liquid water was available. Once the free water was all used up, the mixing ratio of water vapor in the upper atmosphere would fall sharply and the loss rates of both forms of hydrogen, and the take-up of oxygen into minerals, have also declined to the present relatively low levels.

In the present-day atmosphere of Venus, chemical reactions coupled with the transport and radiative processes regulate the abundances of the most important minor constituents. The most important are the cycles involving water vapor, sulfuric acid and their products, which maintain the cloud layers, and which probably also involve reactions between the atmosphere and the surface. However, there are currently very few hard data on the abundances of reactive species near the surface, and still less on the composition and mineralogy of the surface itself. It seems likely, however, that the surface is a net sink for sulfur compounds, the combination of sulfur dioxide with calcite being an example of likely importance in this regard. Similar considerations must apply to interactions between halogen compounds and the surface, since relatively large (compared with Earth) amounts of hydrogen chloride and hydrogen fluoride are present above and below the clouds. Halogen chemistry may also have an important role in the formation of the clouds themselves.

Another important chemical cycle is that which gives rise to the observed distribution of carbon monoxide. CO is very abundant (mixing ratios of the order of a few parts per thousand by volume) in the upper atmosphere of Venus, as would be expected from the action of solar ultraviolet radiation on carbon dioxide. It is strongly depleted in the cloud layers (<1 ppm), again not too surprisingly, since it is involved in reactions with SO_2 and the other species which make up the sulfur cycle. Below the clouds, and near the surface, however, the carbon monoxide values recovers to around 30 ppm, and shows a marked equator-to-pole gradient. It seems likely that CO is transported rapidly down from the thermosphere in the polar vortices (see below) to the troposphere where it is gradually removed by reactions in the hot lower atmosphere and at the surface.

Table 2. Compositions of the terrestrial planet atmospheres.

	Venus	Earth	Mars
Carbon dioxide	0.96	0.0003	0.95
Nitrogen	0.035	0.770	0.027
Argon	0.00007	0.0093	0.016
Water vapor	0.0001(?)	0.01	0.0003
Oxygen	0.0013	0.21	0
Sulfur dioxide	0.00015	0.2 ppb	
Carbon monoxide	0.00004	0.12 ppm	0.0007
Neon	5 ppm	18 ppm	2.5 ppm
Hydrogen chloride	0.5 ppm	3 ppb	<0.1 ppm
Hydrogen fluoride	5 ppm	1 ppb	

Values are given as fractional abundances except where parts per million (ppm) or parts per billion (ppb) are stated.

Thermal structure

The solar radiation which penetrates the clouds warms the lower atmosphere, which is prevented by the opacity of the overlying layers from cooling by radiation to space. It therefore forms a deep convective region, the troposphere (figure 2). This links the high surface temperature of around 730 K, produced by the 'greenhouse' effect as described above, with the level at which the temperature is close to the effective bolometric temperature of Venus (about 230 K), where strong radiative cooling to space can occur. The adiabatic lapse rate, which applies when the vertical gradient is controlled by convection, is $-g/c_p$ (g being the acceleration due to gravity and c_p the specific heat at constant pressure) or about 10 K km^{-1} for Venus, so that the troposphere is around 50 km in vertical extent, much deeper than on Earth or Mars.

Above the troposphere the temperature tends to be constant with height, because the atmosphere here is optically thin and, to a first approximation, each layer tends to find the same equilibrium temperature. The temperature is determined by the balance between the absorption of upwelling infrared from the surface and troposphere and cooling to space, with no significant absorption of direct solar energy taking place.

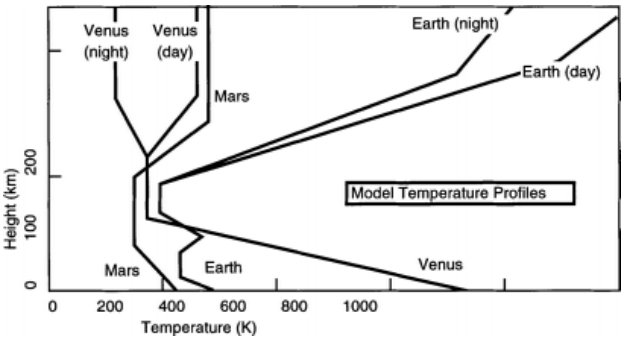

Figure 2. Mean model temperature profiles for the atmospheres of the terrestrial planets.

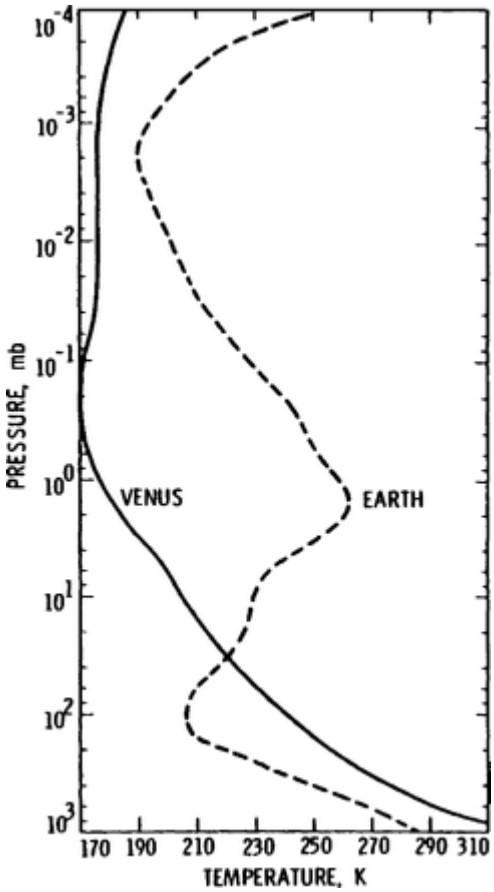

Figure 3. Measured details of the temperature profiles on Venus and Earth, on a common pressure scale.

On the Earth, this situation is altered by the ozone layer, which is responsible for substantial heating which divides the middle atmosphere into the stratosphere, where temperature rises with height, and the mesosphere, where it falls. There is no corresponding effect on Venus (figure 3), except for small amounts of absorption of solar and thermal energy in the near-infrared bands of water vapor and carbon dioxide. The two profiles are quite similar near 1 bar and near 10^{-4} mbar, away from the ozone heating region on the Earth which peaks near 1 mbar.

The tendency for temperature to increase at the top of the range covered by figure 3 marks the base of the thermosphere, which on Venus begins at a height of around 120 km above the surface. Here the atmosphere is very rarefied, and short-wavelength solar radiation and energetic particles drive rapid photochemical reactions and high temperatures by day. When the heating is absent, efficient radiative cooling by CO_2 results in the rapid decline of temperature, so there is a sharp gradient across the terminator, from over 300 K on the illuminated hemisphere down to 100 K or less on the night side.

Data on the planet-wide variability of temperature below the clouds are sparse and are still mainly limited to the small number of direct measurements made by the various entry probes. Remote sensing of the lower atmosphere has recently been shown to be possible, in particular at near-infrared wavelengths, as well as in the microwave, but uncertainties in the distribution of opacity sources in both spectral regions make these difficult to interpret in terms of temperature variations. Such data as exist show that the temperature gradients in the lower atmosphere are close to adiabatic in the vertical, and close to zero in the horizontal, as would be expected theoretically from the high opacity and high density. (However, there must be temperature structure associated with the dynamical activity seen in the deep atmosphere cloud structure—cf figure 5—although this has yet to be measured or even estimated.)

Above the clouds, where the density is lower, more temperature variability is expected, and this has been observed as gradients of the order of several tens of Kelvins on constant-pressure surfaces planet wide. Figure 4 shows the time-averaged (72-day mean) global temperature field from Pioneer Orbiter infrared soundings, in which several features clearly related to the general circulation stand out. Note the 'polar warming', in which the equator-to-pole temperature gradient leads to higher temperatures over pole than equator, in spite of the fact that the trend in radiative heating is in the opposite direction. The 'polar collar' feature stands out in the meridional cross-section; this is an intense ribbon of cold air surrounding the pole at about 65º latitude. These are both features of dynamical origin, related to the zonal super-rotation and the polar vortex respectively. The meridional average temperature field is dominated by the diurnal variation or *solar tide*, the temperature cycle which is induced by the apparent motion of the Sun overhead. This contains a whole spectrum of Fourier components, because the forcing is non-sinusoidal; the actual atmospheric response depends on the mean wind and the interference between the various components. The solar tide on Venus and classical atmospheric tidal theory as originally developed for the Earth (see TIDES) can be reconciled, provided that a realistic representation of the zonal wind is incorporated.

Clouds

Venus is completely enshrouded by clouds in a complex layered structure over 30 km deep; their properties are summarized in table 3. As already noted, the clouds are a key part of a highly interactive climate system (see CLOUDS IN PLANETARY ATMOSPHERES). Concentrated H_2SO_4 droplets have properties which contribute very significantly to the atmospheric 'greenhouse', by scattering conservatively at short (solar) wavelength radiation while strongly absorbing at long (planetary) wavelengths. Changes in the optical properties or depth of the cloud layers, for example if the clouds dissipated

Table 3. Properties of clouds and dust in the terrestrial planet atmospheres.

	Venus	Earth	Mars
Fractional coverage	1.00	0.40	0.05 (cloud); 0–1.0 (dust)
Typical average depth	25–40	5–7	0.01–1.00; 0.2–6 (dust)
Composition	$H_2SO_4 \cdot H_2O$	H_2O	H_2O, CO_2, magnetite etc (dust)
Number density, liquid (cm^{-3})	50–300	100–1000	0
Number density, solid (cm^{-3})	10–50	0.1–50	30–1000 (near surface)
Typical mass loading ($g\ m^{-3}$)	0.01–0.1	0.1–10	0.0002–0.1
Main production process	Chemistry	Condensation	Condensation, windblown (dust)
Equivalent depth (mm)	0.1–0.2	0.03–0.05	1–100
Effective radius (μm)	0.2–30	10	0.4–2.5 (dust)
Main forms	Stratiform	Stratiform, cumulus	Stratiform, mixed (dust)
Temporal variability	Slight	High	High
Dominant heat exchange process	Radiation	Latent heat	Radiation

The equivalent length is the estimated thickness of the cloud material if it were deposited on the surface. The effective radius is the radius of the spherical particles having most nearly the same scattering properties as the cloud at visible wavelengths.

or changed their composition, owing to a reduction in the supply of SO_2 and other source gases from volcanoes, or to an instability in the dynamical regime, would cause the lower atmosphere and surface gradually to cool down (or, conceivably, to become even hotter). Changes in temperature would be likely to further modify the atmospheric circulation and the formation of clouds, producing feedback which seems more likely to be positive (accelerating the change) than negative. At present the radiative, dynamical and chemical processes appear to be in balance, but the stability of the currently observed state may be precarious.

Most of our detailed knowledge of the cloud properties comes from optical measurements: polarimetry

as a function of phase angle from the Earth, nephelometry and particle size measurements from entry probes, and visible, ultraviolet and infrared remote sensing from orbiter and fly-by spacecraft. It has recently been discovered that near-infrared spectroscopic measurements in atmospheric 'windows', that is wavelength regions where the main atmospheric gases are weakly absorbing, penetrate the clouds, in some windows all the way to the surface. This type of observation reveals the cloud morphology all over the planet and shows that the integrated vertical opacity is very variable, by factors of 20 or more. Thick and relatively thin clouds form patterns suggestive of large-scale cumulus dynamics, presumably with the cloud material actively condensing and dissipating in rising and falling air associated with weather systems (figure 5), although the details are lacking because of a shortage of high-resolution data in space and time.

At the PIONEER VENUS Large Probe entry site, the main cloud deck extends from about 47 to about 67 km above the surface, declining gradually at the upper boundary with a scale height of a few km, and with a thin haze layer some 13 km deep below. Within this vertical structure, detailed, and presumably variable, layering occurs and particles of different sizes congregate at different height levels. The particles range in diameter from less than 1 to over 30 μm and tend to a trimodal size distribution, with the commonest diameters falling towards the ends of the overall range and in the 2–3 μm region. It is these intermediate size or 'mode 2' droplets which are visible from outside Venus and for which spectroscopic, polarimetric and other evidence yields a composition of 75% H_2SO_4 and 25% H_2O. The composition of the smaller drops, which form an aerosol haze extending throughout the cloud layer, is unknown. Most of the mass of the clouds is in the biggest drops, for which there is some inconclusive evidence of a non-spherical shape, implying a solid composition, perhaps crystalline sulfur. The formation of the cloud droplets can be explained by a model in which H_2O and SO_2 (the latter possibly of volcanic origin) combine photochemically near the cloud-top level. It is more difficult to explain the size distribution, particularly the existence of more than one mode. Compositional contrasts and dynamical effects may be at work but once again the observations which would elucidate these are lacking.

There is some evidence in infrared maps from the Pioneer Venus orbiter of cold, high cloud, presumably condensed CO_2, near the tropopause above the dawn terminator, where the atmosphere is coldest as it comes to the end of the long (>50 h at this altitude) Venus night.

Figure 5. 2.7 μm image of Venus from Galileo–NIMS.

Dynamics

As a result of the slow rotation of the planet, its near-circular orbit and small obliquity, the underlying circulation of Venus' atmosphere is quite simple. The Sun is always above the equator, to within a couple of degrees, so the air warmed at low latitudes rises and moves towards the poles, where it cools and descends before returning equatorwards at lower altitudes.

On top of this simple picture are superimposed various complications. One that has been observed for many decades, but remains difficult to explain, is the global 'super-rotation', which manifests itself in cloud structure which moves rapidly around the planet in a direction parallel to the equator. The cloud markings, which appear with high contrast through an ultraviolet filter, have their origin at heights 50 or 60 km above the surface (where the pressure is of the order of 100 mbar) and travel around the equator in 4–5 days, corresponding to speeds near 100 m s^{-1}. This is more than 50 times faster than the rotation rate of the surface below. Measurements of the winds below the clouds, and calculations (from temperature data) of the winds above the cloud tops, show that the zonal wind speed declines at higher and lower levels, reaching values near zero at about 100 km and near the surface respectively.

Direct measurements of the winds 1 m or so above the surface by the Russian landers Venera 9 and 10 found

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

velocities of ≤1 m s^{-1}. Tracking of the Pioneer and Venera landers during their descent showed that there is a steady decrease with height from the 100 m s^{-1} or so observed in the ultraviolet markings near the cloud tops. Earth-based observers had earlier shown, by the measurement of Doppler-shifted emission lines from atmospheric gases, that the cloud-tracked winds do, in fact, apply to mass motions, rather than the phase speed of waves as had also been suggested.

Attempts have been made to explain these high zonal wind speeds on Venus by several mechanisms, all of which fall into one of three main categories, i.e. (i) the gravitational interaction of the Sun with the atmospheric tides, (ii) the overhead motion of the Sun in the sky (the 'moving flame' mechanism) and (iii) the upward transport of momentum from the surface. Currently prevailing opinion favors a version of mechanism (iii), in which momentum from the solid planet is transported by waves whose interaction with the main flow is complex and in which the mean meridional circulation plays an important role. Parameterizations have been found which are able to produce large zonal velocities in dynamical models of the Venusian atmosphere, although of course this is not the same as saying that we understand the forcing or dissipation mechanisms responsible for the transfer of momentum from the surface to the cloud tops.

The cloud motions which trace the zonal winds also reveal the pattern of the meridional circulation on Venus. As expected on the simple theoretical grounds outlined above, Hadley cells exist in each hemisphere. These are global-scale circulation cells characterized by rising motion all around one constant latitude belt and descending motion at another. Each cell extends to higher latitudes than on Earth, in part a consequence of the slower zonal rotation speeds. Near the poles on Venus, a complex instability develops, resulting in dramatic long-lived wave structures. The *polar collar* takes the form of a band of very cold air, some 10 km deep and 1000 km in radius, centered on the pole. Inside the collar, temperatures are some 40 K cooler than outside the feature. Poleward of the inner edge of the collar lies the *polar dipole*, a wavenumber 2 feature consisting of two well-defined warm regions circulating around the pole. Both the dipole and the collar have so far resisted attempts to model them as normal modes of the atmosphere.

The cloud-tracked winds obtained from Pioneer Venus and Mariner 10 both show equator-to-pole velocities of around 5 m s^{-1} in each hemisphere. Tracking of the Pioneer Venus probes shows winds of this magnitude at about 50–60 km altitude, with a very complicated vertical structure (figure 6). One possible interpretation of the alternations in the direction, as well as the magnitude, of the meridional wind is that these could mark the passage of the probe through the different components of a stack of Hadley cells, each extending from the equator to high latitudes. The layered eddy sources and sinks which could drive the zonal super-rotation may be related to the cell interfaces.

Motions in the deeper atmosphere were observed by near-infrared imaging carried out by the Galileo probe in 1990. The features observed on the night side of the planet at wavelengths from 1 to 3.5 μm originate in the main cloud deck, illuminated from below by thermal emission from the hot lower atmosphere. The typical velocities inferred near the equator were about half as fast as those from UV markings, which is consistent with the vertical profiles of wind and cloud opacity measured by the Pioneer and Venera probes, since the cloud layer providing most of the opacity in the case of the near-IR markings is 10–15 km deeper than for the UV markings. Galileo winds feature a zonal jet of more than 100 m s^{-1} at middle latitudes and equator-to-pole drifts of a few m s^{-1}.

Conclusion

Venus presents an arresting picture. What we appear to see is an Earth-like planet whose atmosphere failed to

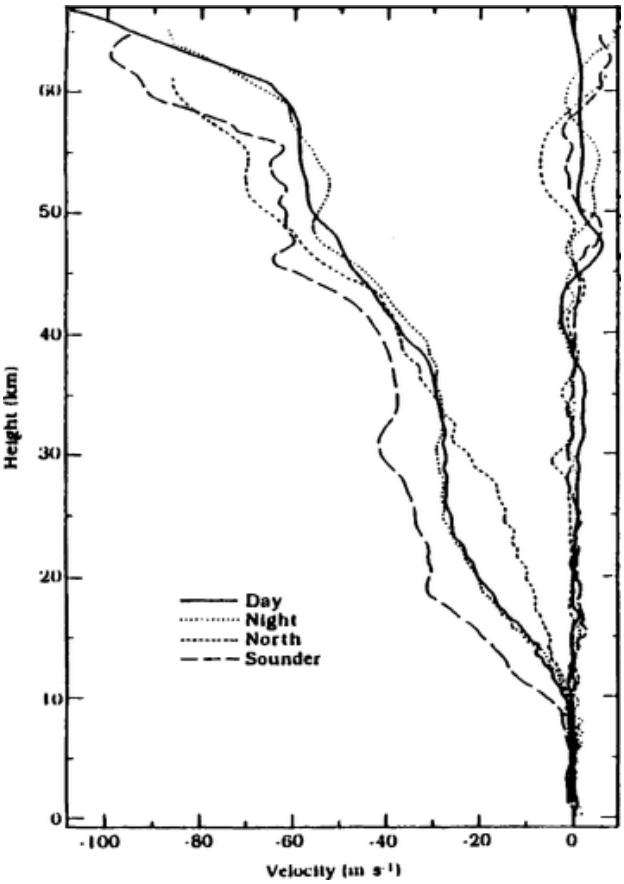

Figure 6. Profiles of the zonal (east-to-west) and meridional (north-to-south) wind on Venus as measured by tracking the descent of the Pioneer Venus probes.

evolve in the same way, primarily because of the early loss of water, and which now supports a thick, primitive atmosphere in rapid, turbulent motion. Thick, sulfurous clouds, probably originating in volcanic activity on the surface and possibly requiring present-day volcanism for their maintenance, blanket the planet. The resulting 'greenhouse' effect drives the surface temperature to remarkably high levels.

These conditions make exploration difficult since remote sensing is inhibited (but not prevented altogether) by the clouds, while landings are arduous and short lived. Advanced techniques are under development that will allow sample return from Venus' surface and clouds and submarine-like 'aerobots' to cruise in the hot, thick lower-atmospheric regions. New remote-sensing techniques for the lower atmosphere will be applied from orbit.

The focus of this new generation of Venus atmospheric studies will be an understanding of the dynamical regimes present, the photochemistry of the clouds, the scale of volcanism on Venus and the question of whether or not our sister planet once had oceans, like the Earth. Above all, however, will be the need to understand the dynamical regimes present. Knowledge of even the principle of the origin and maintenance of the zonal super-rotation is lacking; the same is true of the spectacular giant vortices in the high-latitude regions, in particular the phenomena known as the polar collar and the polar dipole. The deep atmosphere shows huge weather systems whose very existence was unsuspected until about a decade ago and for which there exists no theoretical basis at all. How can such a simply rotating, nearby, Earth-like planet be in such an incomprehensible state?

Breaking news update (30 April 2002)

Scientists have captured the first x-ray view of Venus using NASA's CHANDRA X-RAY OBSERVATORY. The observations provide new information about the atmosphere of Venus. Venus in x-rays looks similar to Venus in visible light, but there are important differences. The optically visible Venus is due to the reflection of sunlight and, for the relative positions of Venus, Earth and Sun during these observations, shows a uniform half-crescent that is brightest toward the middle. The x-ray Venus is slightly less than a half-crescent and brighter on the limbs. The differences are due to the processes by which Venus shines in visible and x-ray light. The x-rays from Venus are produced by fluorescence, rather than reflection. Solar x-rays bombard the atmosphere of Venus, knock electrons out of the inner parts of the atoms, and excite the atoms to a higher energy level. The atoms almost immediately return to their lower energy state with the emission of a fluorescent x-ray. A similar process involving ultraviolet light produces the visible light from fluorescent lamps. For Venus, most of the fluorescent x-rays come from oxygen and carbon atoms between 120 and 140 km (74 to 87 mi) above the planet's surface. In contrast, the optical light is reflected from clouds at a height of 50 to 70 km (31 to 43 mi). As a result, Venus' Sun-lit hemisphere appears surrounded by an almost-transparent luminous shell in x-rays that appears brightest over the limb.

Bibliography

Two major surveys of Venus have been published in recent years. The reader is referred to the atmospheric chapters in these for a more detailed overview of current knowledge and problems and for a complete set of references to original work.

Venus: Interaction with Solar Wind

The solar wind interaction with VENUS provides the archetypal interaction of a flowing magnetized PLASMA with a PLANETARY IONOSPHERE. Mars interacts with the solar wind in much the same way as does Venus, while the rotating plasma in the Saturnian magnetosphere is believed to interact similarly with its moon, Titan (see SATURN: MAGNETOSPHERE INTERACTION WITH TITAN). The interaction of the Jovian plasma with its moon Io is intermediate between the cometary and Venus interactions (see IO: PLASMA TORUS). From a more academic perspective, this interaction illustrates how a magnetized plasma interacts with an unmagnetized plasma, and how mass pickup (of planetary ions, in this case) affects a flowing plasma. Our understanding of the interaction has been built up over a series of flight missions: Mariner 2 and 5, Venera 2, 4, 6, 8–14 and Pioneer Venus. The latter mission remained in orbit for 14 yr investigating the solar wind interaction with Venus over a complete solar cycle.

Although Venus is famous for its sulfuric acid clouds and sulfur dioxide haze, its main atmospheric constituent is carbon dioxide of mass 44. Because Venus is similar to the Earth in mass and size (6051 km radius), we might expect *a priori* its atmospheric behavior to be similar. Paradoxically, while the lower atmosphere is much warmer than the terrestrial atmosphere owing to the greenhouse effect, the upper atmosphere of Venus, above 100 km, is much cooler than that of Earth because of the absence of heating by a magnetosphere at Venus (see VENUS: ATMOSPHERE). As a consequence the scale height of the neutral Venus atmosphere is quite small. In the cold (cryosphere) nightside it is only a few km. In general, the atmospheric density falls off according to the equation of hydrostatic equilibrium that balances the upward pressure gradient force with the downward force of gravity on that parcel of gas:

$$nmg = -\frac{\mathrm{d}nkT}{\mathrm{d}h}$$

where n, m, g, k, T and h are respectively the number of molecules per unit volume, their mass, the force of gravity, Boltzmann's constant, their temperature and the altitude of the point of interest.

For an isothermal atmosphere the density decreases as

$$n = n_0 \exp(-h/H_n)$$

where $H_n = kT/mg$. The isothermal description fails at the highest altitudes (above about 200 km) for some constituents, such as atomic oxygen, where nonthermal processes, notably dissociative recombination of O_2^+, increase the average temperature. The important nonthermal processes are both photochemical (e.g. involving neutralization of ionospheric ions and electrons produced by solar EUV radiation) and 'mechanical' (involving collisions of energetic particles from above with the ambient gas). Thus atomic oxygen at Venus has a cold component, with a scale height of a few tens of km, and a hot component that extends to high altitudes with a scale height of hundreds of km. This latter component plays a special role in the solar wind interaction, described below.

As on Earth the Venus upper atmosphere is partially ionized by solar ultraviolet radiation and energetic particles that enter from the surrounding space. The rate of ionization decreases rapidly with decreasing altitude at low altitudes where the ionizing radiation and particles are absorbed. It also decreases with increasing altitude at high altitudes where the ionizing radiation is constant but the ionizable neutral particles decrease with altitude. Thus there is a maximum ion production rate at some altitude h_m. The rate of ionization, Q, varies with altitude for a simple one-component isothermal ionosphere as

$$Q = Q_m \exp[1 - y - \exp(-y)]$$

where Q_m is the peak production rate and $y = (h–h_m)/H_n$ where H_n is the neutral scale height and h_m is the height of peak production. This function is sketched for a scale height of 25 km in figure 1, representative of oxygen in the warmer dayside upper atmosphere of Venus. If the ionosphere is in photochemical equilibrium in which the recombination of electrons and ions takes place without vertical transport, then the rate of recombination is proportional to the product of the electron and ion number densities which are equal in our simple ionosphere. Hence the electron number density is

$$N_e = N_{m0} \exp\{[1 - z - \sec\chi \exp(-z)]/2\}$$

where χ is the solar zenith angle and we have referenced the density to the maximum at the subsolar point, N_{m0}, and the normalized altitude, z, to its altitude, h_{m0}, and the scale height, H_n. This function is shown in the bottom panel of figure 1.

At Venus the high-altitude ionospheric electron temperature is about 5000 K. The peak of the dayside ionosphere is at an altitude of about 140 km and has a peak number density of just under 10^6 cm$_{-3}$. At 400 km the number density is about 20 000 cm$_{-3}$ under solar maximum conditions near the subsolar point. At this altitude the collision rate is quite low and the electrical conductivity quite high. This is important for the solar wind interaction because the solar wind is a magnetized plasma. When it flows against the Venus ionosphere it does not generally penetrate below about 400 km unless the solar wind conditions are disturbed. The ionospheric pressure at 400 km under solar maximum conditions is sufficient to stand off the typical dynamic pressure of the

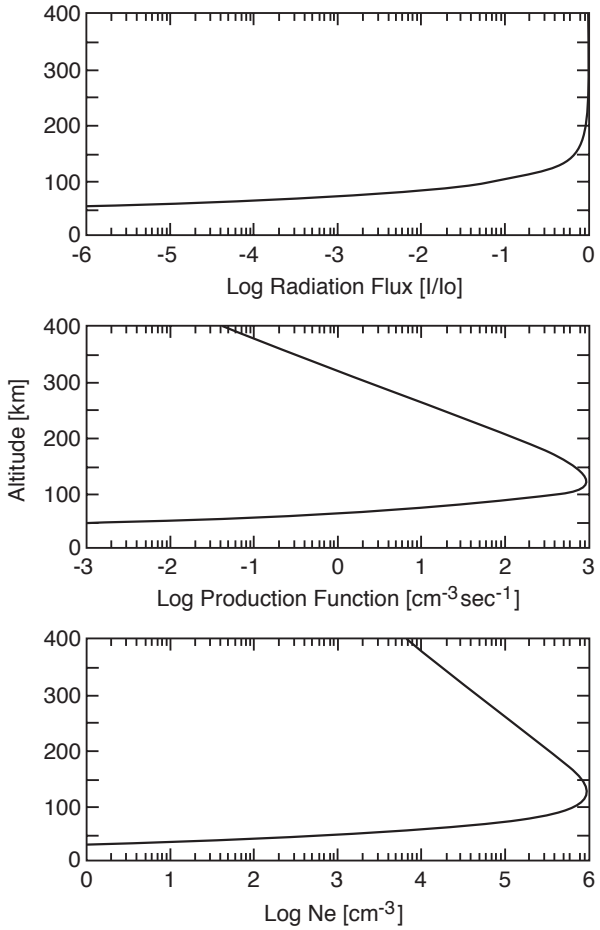

Figure 1. The formation of a Chapman-layer' ionosphere. Top: UV radiation from Sun drops in intensity as it is absorbed in photoionization process. Middle: Rate of electron production with altitude. As altitude decreases, the rate first increases owing to the increasing atmospheric density and then decreases when the UV radiation is exhausted. Bottom: The electron density consistent with the production if there is no vertical or horizontal transport.

solar wind. This is not expected to be the usual case at solar minimum when the ionospheric pressure is less.

The SOLAR WIND is a supersonic flow of electrons and ions with a number density near the orbit of Venus of about 15 particles per cm^3, a velocity of about 440 km s_{-1}, an ion temperature of about 10^5 K, an electron temperature of about 2–10^5 K and a magnetic field strength of about 10 nT. The velocity of a wave that could compress the solar wind flow and deflect it around Venus is about 100 km s^{-1} or about 1/4 of the speed of the solar wind. Thus, the deflection has to occur via the formation of a standing shock wave whose strength is measured by the ratio of the compressional wave velocity to the incoming flow velocity. This interaction is sketched in figure 2. The Venus bow shock has a shape similar to Earth's bow shock shape but, because the obstacle producing the shock is in this case the planetary ionosphere (and not an

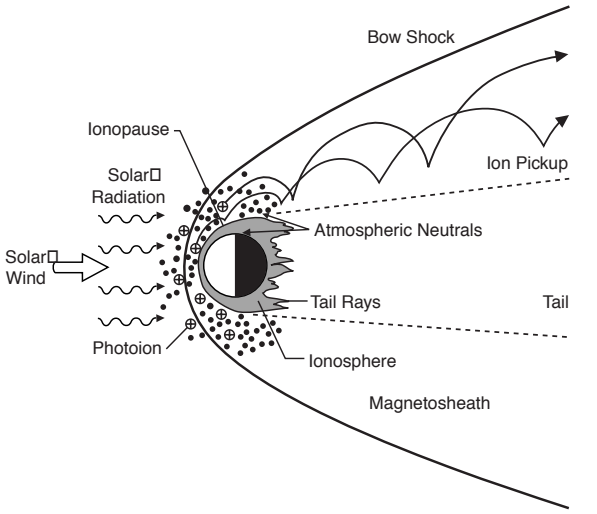

Figure 2. The solar wind interaction with the Venus ionosphere and neutral atmosphere. The solar UV ionizes the atmosphere and the ionosphere deflects the solar wind. Some neutral atoms are ionized in the solar wind and are picked up by the electric field.

internal magnetic field), the size of the bow shock is much smaller (see MAGNETOSPHERE OF EARTH: BOW SHOCK). At the nose of the Venus shock the Mach number or shock strength is close to 4 under typical conditions.

In the ideal case when none of the solar wind is absorbed by Venus and no ions are added to the flow by the atmosphere of Venus, the shock front, or bow shock as it is called, stands off from the obstacle at a distance sufficient to allow all the material that is compressed and deflected by the shock to flow around the obstacle. When the shock is strong, the density of the solar wind flow can increase a factor of 4 across the shock. At solar maximum when the pressure of the ionosphere is high, the shock front is about 2000 km above the surface of Venus at the subsolar point. If the shock weakens, the density jump becomes less and the shock moves away from the planet. In the limit as the Mach number approaches unity, the shock moves away to infinity. At solar minimum the typical ionosphere does not have sufficient pressure to prevent some direct interaction of the solar wind with the neutral atmosphere and the shock moves closer to Venus as some solar wind is absorbed by Venus.

The shocked plasma immediately downstream from the shock front is simply heated and compressed solar wind whose properties can be calculated by a set of magnetohydrodynamic equations called the Rankine–Hugoniot equations. However, the flow velocity perpendicular to the magnetic field direction drops drastically as the subsolar point on the obstacle is approached. The magnetic field of the solar wind plasma is compressed as the stagnation point is approached, and the field becomes draped around the obstacle. The thermal velocity of the particles is then able to evacuate the field lines

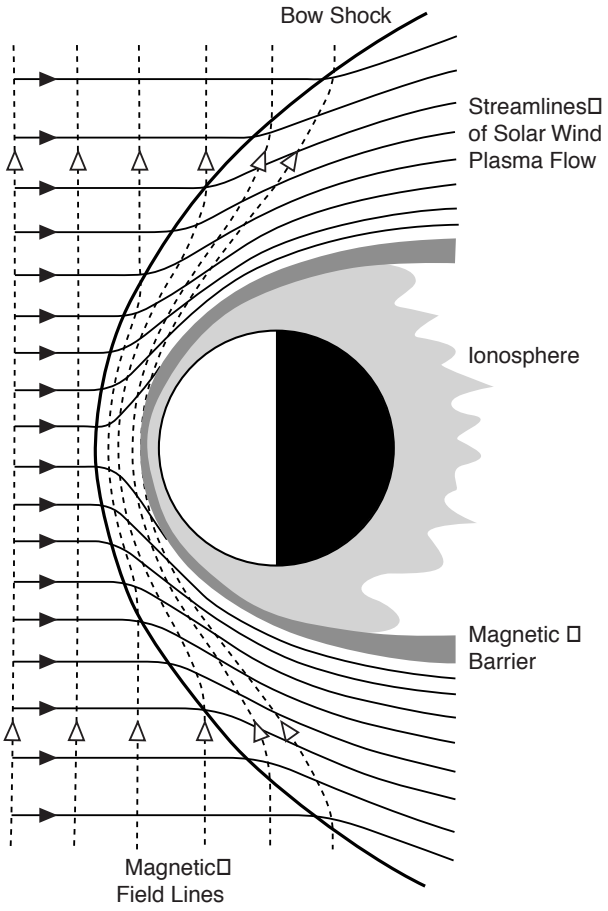

Figure 3. The solar wind flow and interplanetary magnetic field as it interacts with Venus, leading to the formation of a magnetic barrier.

so that the inner edge of the shocked plasma, or magnetosheath, becomes a magnetic barrier in which the transverse pressure is exerted almost totally by the magnetic field and not by the thermal plasma pressure. A similar situation occurs in what is called the 'depletion layer' just outside Earth's magnetosphere. As sketched in figure 3 the magnetic field wraps around Venus, maintaining a barrier between the flowing solar wind and the ionosphere and contributing to the formation of a magnetic tail in the antisolar direction. The plasma in the magnetosheath accelerates with distance behind Venus and the shock expands and weakens. Eventually far behind Venus the solar wind that interacted with Venus is indistinguishable from solar wind that did not interact, as long as Venus did not add anything to the solar wind flow.

Even though the bow shock marks the upper extent of the pressure wave that Venus launches to deflect the solar wind, there still are phenomena that can be seen in advance of the bow shock. These upstream phenomena consist of charged particles and waves. The particles are electrons and ions that either were reflected at the shock

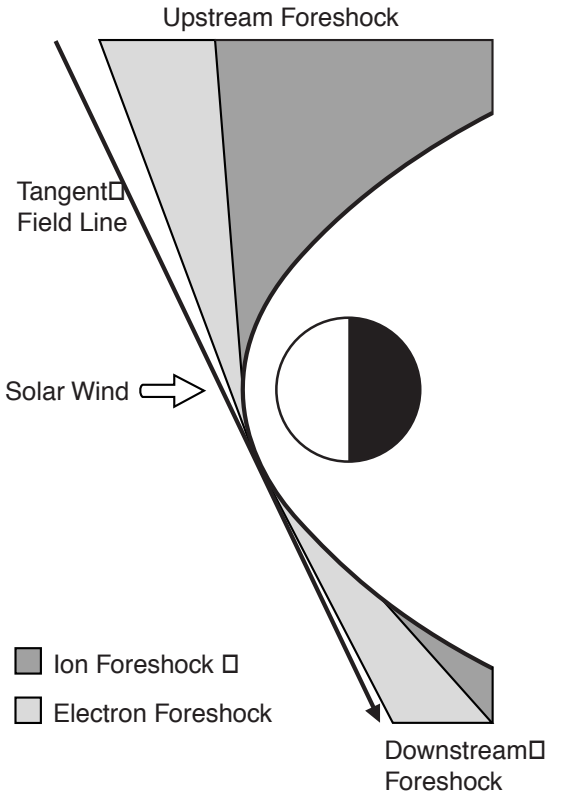

Figure 4. The geometry of the electron and ion foreshock at Venus. These regions mark the field lines that intersect the shock and along which electrons and ions can reach a spacecraft at the velocities to which they have been accelerated.

or leak from the hot population behind the shock and move upstream against the solar wind flow. The geometry of this region is sketched in figure 4. The waves can either be generated by the backstreaming particles (and generally be convected toward the shock) or be generated at the shock and move upstream. In many respects the wave and particle phenomena in front of the Venus bow shock are the same as those generated in front of the bow shocks of magnetized planets including Earth. The nature of the obstacle is not important here.

Returning to the obstacle for a moment, we note that the magnetic barrier has the effect of maintaining a cap on the ionosphere. This upper boundary is called the ionopause. Ionospheric plasma is not detected above the barrier because the atmospheric ions produced there are immediately removed by the interplanetary electric field (equal to $-V_{sw}B$), either swept away from Venus or deposited into the deeper atmosphere. Two such ions are sketched in figure 2. Nevertheless, most ions are produced within the ionosphere and remain in the ionosphere proper until they recombine. At comets the opposite is true. The recombination rate at high altitudes in a planetary ionosphere is small so that in steady state ions must flow to low altitudes to recombine. In the subsolar region the typical motion of

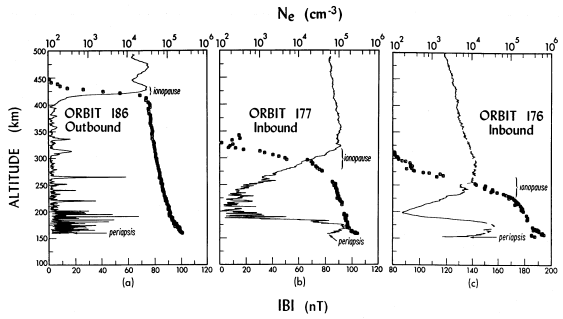

Figure 5. Vertical profiles of the electron density, N_e (symbols), and magnetic field strength, B, (full curve), on days of low (left), moderate (middle) and (high) solar wind pressure. Measurements by the Pioneer Venus orbiter on three early orbits when the spacecraft was entering the dayside ionosphere and periapsis, the closest approach to the planet, were at low altitudes.

the ionosphere is downward. There are few ions created at any altitude in the Venus shadow so that the nightside ionospheric pressure is much less than on the dayside. Away from the subsolar region the pressure gradient induces a supersonic expansion of the upper ionosphere into the nightside whenever the ionosphere is present at altitudes of 400 km and above. This flow produces a significant nightside ionosphere even though little ionosphere is produced there. At solar minimum or when the solar wind dynamic pressure is high the ionopause is too low to allow horizontal transport to the nightside ionosphere, which becomes very weak as a result.

Complications

The above description is a correct first-order model of the Venus interaction but there are details that need to be added to complete the picture. We look first at the variations in the ionosphere caused by varying solar wind pressure. We then examine the effects of planetary ion mass added to the solar wind flow and finally examine how the interaction varies with the solar cycle.

The effect of varying pressure

The boundary between the magnetic barrier and the ionosphere, the ionopause, is generally a thin current layer, at least when the solar wind pressure is low and the ionopause altitude is high (about 400 km). This thickness appears to be about one ionospheric thermal ion gyroradius. As mentioned above, the electrical conductivity is so high under these conditions that there is no diffusion of the draped solar wind magnetic field across the ionopause current layer. The left-hand panel of figure 5 shows such a situation illustrated with vertical profiles of the magnetic field and plasma density seen by the Pioneer Venus orbiter. Nevertheless, magnetic field can apparently get into the ionosphere in the form of flux bundles or ropes. These flux ropes cause the large spikes in field strength that are seen low in the ionosphere in the left-hand panel of figure 5. Observations suggest that they are untwisted at high altitudes but become twisted and even kinked as they sink. Figure 6 illustrates the for-

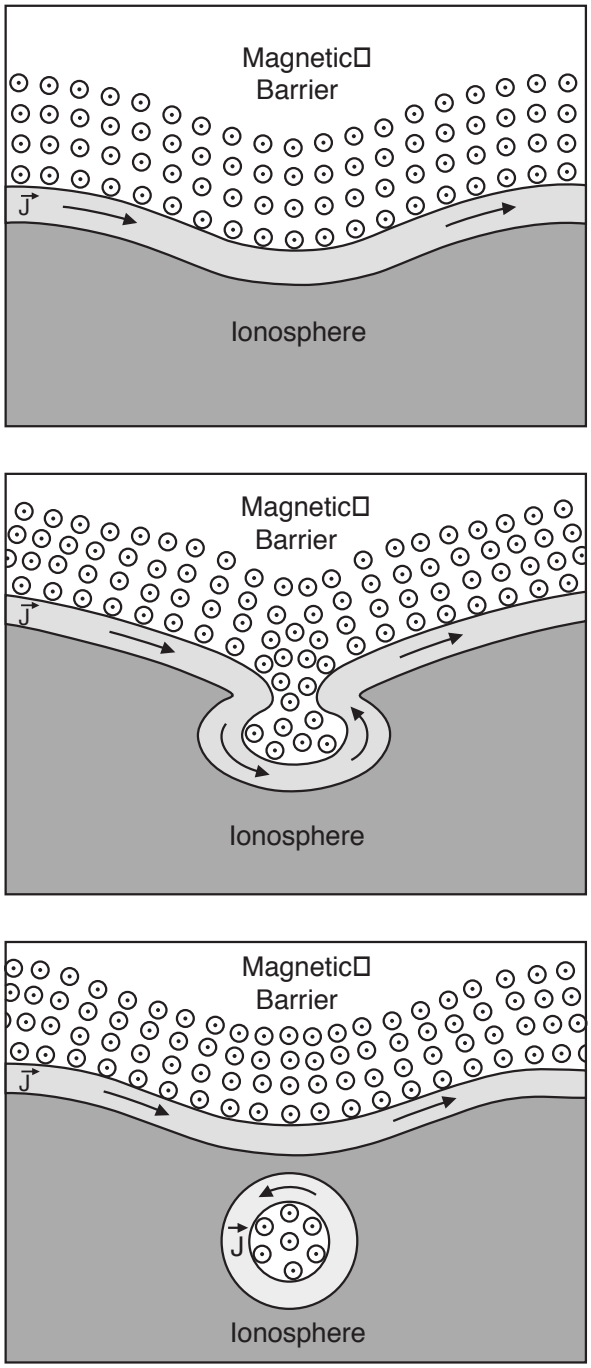

Figure 6. Formation of a flux rope in the Venus ionosphere due to the sinking of an initially buoyant flux tube from the magnetic barrier. In the middle panel the flux tube has become heavier owing to mass addition through photoionization of the neutral ionosphere and sinks. The magnetic force due to the curvature in the plane perpendicular to the page accelerates this motion.

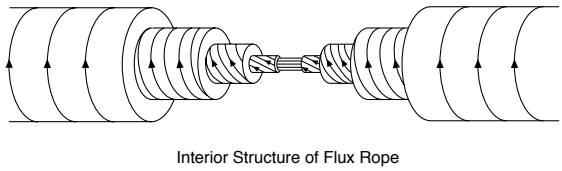

Figure 7. The magnetic structure of a flux rope. In the interior the magnetic field is strong and parallel to the axis of the rope. In the outer parts of the rope the magnetic field is weak and wraps around the axis.

mation of one of these ropes from an originally buoyant flux tube of the magnetic barrier. The twist in the ropes helps to maintain the coherence of the rope and to balance the outward pressure of the magnetic field. The twist is believed to arise as the rope sinks through a vertical shear in the horizontal velocity of the ionospheric plasma. Often the magnetic field of the ropes is almost in force balance by itself so pressure gradient forces in the plasma are not important. Such ropes are called force free. A sketch of the magnetic structure of such a flux rope is shown in figure 7.

Because the ionopause forms where pressure balance with the solar wind pressure occurs, its height varies with solar wind conditions. As illustrated by the rightmost two panels of figure 5, when the solar wind pressure increases to about 20 nPa and the altitude of the ionopause current layer falls to 250 km or less, the current layer thickens and magnetic field diffuses into the ionosphere because of ion–neutral and electron–neutral collisions. The downward ionospheric plasma velocity near the subsolar region carries the magnetized plasma to low altitude where it recombines and deposits the magnetic flux. Thus the collisional Venus ionosphere can become magnetized from the ionopause down to the peak of the ionosphere. The magnetic flux then collisionally diffuses through the current layer at the bottom of the ionosphere, creating a magnetic field between the ionosphere and the planet's core. The diffusion of magnetic flux below the dayside ionopause is balanced by the upward diffusion of magnetic field on the nightside. Since field lines in the ionosphere generally have their ends in the solar wind, these field lines on the nightside have ends that have moved far down the magnetotail. Hence the field lines are mainly vertical or radial on the nightside and close beneath the ionosphere. These regions of radial magnetic field on the nightside prevent the plasma from entering these regions so that they appear as 'holes' in the plasma measurements. The magnetic pressure in the holes is enhanced by the amount that the plasma pressure is diminished so that the plasma and field pressures are in equilibrium.

If the dayside ionosphere becomes fully magnetized, then the flow of plasma from the dayside to the nightside is cut off. Under those circumstances the nighttime plasma density drops to very low values and the phenomenon called a 'disappearing' ionosphere results. This same situation prevails at solar minimum when the dayside ionospheric pressure is lower than the typical solar wind pressure. The magnetic structure of the ionosphere under these low and high solar wind dynamic pressure conditions (relative to ionospheric plasma pressure) is shown in figure 8.

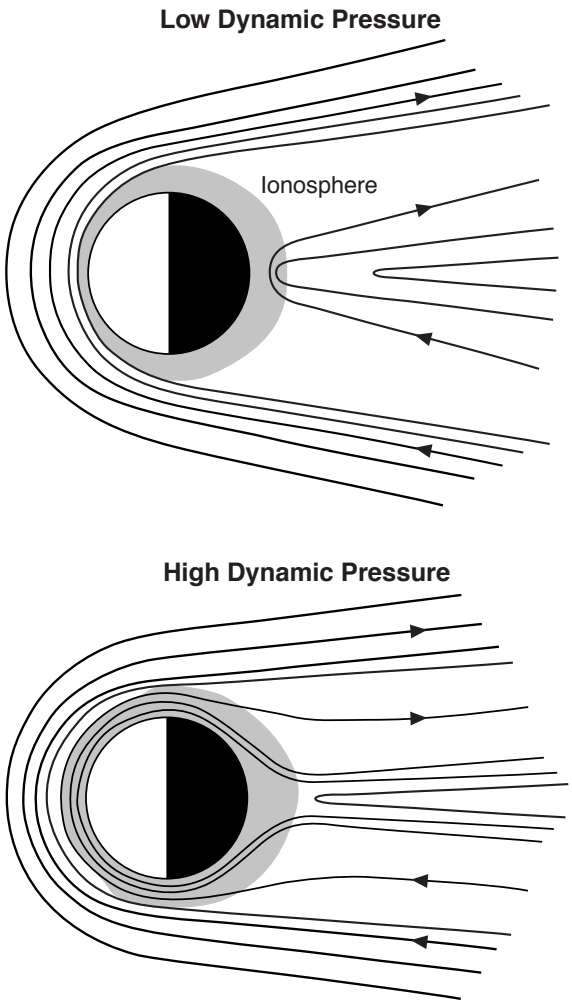

Figure 8. The magnetic configuration of the Venus ionosphere at times of low (top) and high (bottom) solar wind dynamic pressure.

Mass addition to the solar wind flow

The interaction of a comet with the solar wind is well understood (see SOLAR WIND: INTERACTION WITH COMETS). Gas sublimes from the comet nucleus and expands rapidly into the relative vacuum of space. This gas is ionized and swept up by the solar wind. The mass addition to the solar wind in the form of cometary ions slows it down by the conservation of momentum. The ends of the interplanetary field lines threading the cometary atmosphere are rooted in the undisturbed solar wind and thus carried past the comet at the solar wind speed.

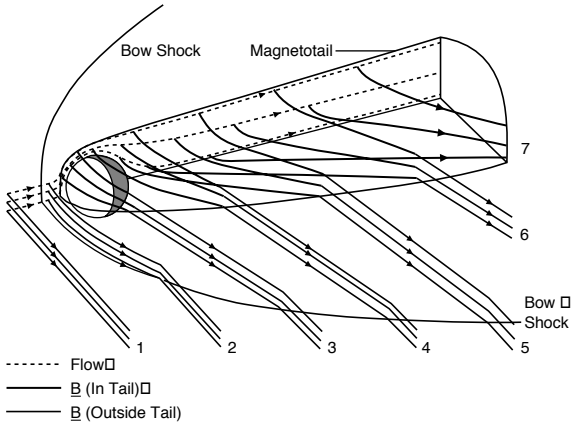

Figure 9. The formation of the Venus magnetotail. Flux tubes that pass closest to Venus are slowed the most, while their ends are carried along in the solar wind.

A long tail is formed downstream of the nucleus as a result.

The rate of addition of mass by Venus to the solar wind is much less than that of a comet because the planet's gravitational pull prevents the atmospheric gas from expanding rapidly and keeps it close to the planet. Nevertheless, as noted above, Venus does have a neutral oxygen exosphere that extends to at least 4000 km. Ions produced above the ionopause, by photoionization or collisions with the solar wind particles themselves, interact directly with the solar wind. The atomic oxygen exosphere is produced by the ionosphere, in particular by the dissociative recombination of O_2^+ ions at lower altitude, in which ions recombine with an electron to form two suprathermal oxygen atoms. These atoms have enough energy to allow them to reach altitudes above the ionopause where, if ionized, they will be carried away in the magnetosheath or solar wind flow. This additional ion mass can slow down the flow near the magnetic barrier where the ion production is highest owing to the greater neutral densities there. A larger region of stagnation could increase the size of the barrier and push the shock away from the obstacle. It could also add additional magnetized plasma to the ionosphere and enhance the magnetic tail. As illustrated in figure 9 the magnetic field lines approaching closest to Venus are slowed down in their motion at closest approach while their ends in the undisturbed solar wind are carried away at the solar wind velocity. This produces a long comet-like 'induced' tail.

The ions on these field lines are eventually accelerated up to the solar wind velocity. However, the composition of these ions always tags them as Venus ions. The Venus magnetic tail was regularly detected at the apogee of the PIONEER VENUS spacecraft (12 Venus radii) but the ions have been detected as far away as the orbit of the Earth.

The draped magnetic field will apply a stress to the plasma surrounding Venus but under steady-state conditions this stress should be rather uniform. When the magnetic field changes direction the uniformity of this stress changes and ridges and enhancements at the ionospheric plasma–solar wind boundary can form. When spacecraft pass through such a structure, the density enhancement may appear to be a 'cloud' of ionospheric plasma near the ionopause. These clouds stretch out from the nighttime ionosphere of Venus and are correlated with interplanetary magnetic field rotations. Other filamentary structures of ionospheric plasma extend out of the nightside upper ionosphere when solar wind conditions are steady. These 'tail rays' may represent a low-altitude component of planetary ions picked up by the solar wind from the denser cold upper atmosphere.

A final phenomenon that has been seen at Venus that appears to be associated with the solar wind interaction is the Venus aurora. On Earth AURORAS are often associated with parallel electric fields that accelerate electrons down into the atmosphere causing atoms to be excited and to emit photons. Weak, patchy auroras exist on the nightside of Venus also, but no explicit cause of these auroras has been determined.

Solar cycle variation

The above discussion enables us to now address how Venus responds to the solar cycle changes on the Sun. The Earth's solar wind interaction is sensitive to the SOLAR CYCLE mainly because there are more coronal mass ejections launched from the Sun near solar maximum than solar minimum. The Venus interaction is also sensitive to these episodic, mainly magnetic, structures (albeit in very different ways than is Earth's magnetospheric interaction), but it is more generally sensitive to the changing ultraviolet flux during the solar cycle. At solar minimum the ionosphere is not as well developed, and so the same solar wind pressure results in an ionopause deeper in the atmosphere where the ionosphere is less highly electrically conducting. This routinely magnetizes the dayside ionosphere and drastically reduces the flow to the nightside ionosphere. The obstacle becomes a little smaller but more importantly some of the solar wind is probably absorbed. Thus the solar wind does not have to be deflected so far above the planet as at solar maximum. This effect is so marked that the shock approaches to within 1000 km of the planet of solar minimum as sketched in figure 10.

At solar maximum the dayside ionosphere is denser and better able to stand off the solar wind plasma above the ionosphere. In addition the neutral exosphere of hot oxygen is denser and more ions are created within the magnetosheath itself. This extra ionization further enhances the deflection of the solar wind.

Web Update (31 July 2002)

Scientists have captured the first x–ray view of Venus using NASA's CHANDRA X-RAY OBSERVATORY. The observations provide new information about the atmosphere of Venus. Venus in x–rays looks similar to Venus in visible light, but there are important differences. The optically visible Venus is due to the reflection of sunlight and, for the relative positions of Venus, Earth and Sun during these observations, shows a uniform half–crescent that is brightest toward the middle. The x–ray Venus is slightly less than a half–crescent and brighter on the limbs. The differences are due to the processes by which Venus shines in visible and x–ray light. The x–rays from Venus are produced by fluorescence, rather than reflection. Solar x–rays bombard the atmosphere of Venus, knock electrons out of the inner parts of the atoms, and excite the atoms to a higher energy level. The atoms almost immediately return to their lower energy state with the emission of a fluorescent x–ray. A similar process involving ultraviolet light produces the visible light from fluorescent lamps. For Venus, most of the fluorescent x–rays come from oxygen and carbon atoms between 120 and 140 km (74 to 87 mi) above the planet's surface. In contrast, the optical light is reflected from clouds at a height of 50 to 70 km (31 to 43 mi). As a result, Venus' Sun–lit hemisphere appears surrounded by an almost–transparent luminous shell in x–rays that appears brightest over the limb.

Venus: Surface

Because of its thick and dense atmosphere, VENUS has only very recently revealed the aspect and the characteristics of its surface. In fact, the only means to penetrate the atmosphere and to see what is underneath is to observe the planet in wavelength regions of the electromagnetic spectra where the atmosphere is transparent such as the radar centimetric wavelengths or some near-infrared windows around 1 micron. An alternative solution is to send probes that directly land on the surface. These two means have been used to explore the surface of Venus and they give two complementary kinds of information. The first gives global and large-scale information about the surface, such as topography, surface roughness, altimetry, etc, while the second gives very local information such as surface images and/or composition. These two complementary techniques have greatly enhanced our knowledge of the surface of Venus and of its history.

The Venus coordinate system

The map coordinate system used for measuring longitude on Venus is different from that used on Earth. On Earth, longitude (an imaginary line stretching from pole to pole) is measured from a starting point (the prime meridian) at Greenwich, England (near London), toward the east and toward the west with increasing values in degrees until east meets west at the 180° point (the dateline), which is diametrically opposed to Greenwich. On Venus, longitude is measured from 0 to 360 degrees with the prime meridian centered within a small impact crater named Ariadne, located in Sedna Planitia. There is an arbitrary convention that determines the direction of increasing longitude on planetary bodies other than Earth: longitude shall be measured in a direction opposite to that in which the planet rotates. Because Venus rotates in a clockwise direction as viewed looking down on the north pole, longitude on Venus increases in numerical value toward the east from the planet's prime meridian.

Large-scale observations

Most of the large-scale and global observations of the Venusian surface have been obtained by radar. There are different kinds of radar data: (a) altimetric data, (b) reflectivity data and (c) emissivity data. The first gives the altitude of the topography, the second gives information about the roughness of the surface and the last gives information about the brightness of the surface.

The first reflectivity data for the Venusian surface were obtained from ground-based radar observatories. The first images were acquired in 1972 from the Goldstone satellite radar tracking system located in California. Observations with the Goldstone station were made until 1988 covering essentially the equatorial regions between 15°N and 15°S latitude and 260°E and 30°E (through 0°) longitude. The spatial resolution, that was of the order of 5–10 km in the first images, has been improved to near 1 km in the data acquired since 1986. The second ground-based observations from the Venusian surface come from the Arecibo observatory in Puerto Rico. On this site, the first reflectivity images were taken in 1975 and the last in 1988. With these data, that covered latitudes up to 50°N, the spatial resolution was 1.5 km. From space, the first almost global observation of the surface of Venus was obtained by the NASA PIONEER VENUS Orbiter that arrived at the planet on 4 December 1978. Around 93% of the surface was covered between 74°N and 63°S latitude. These observations gave the first large-scale altimetric and topographic coverage with an altimetric precision of 150 m at a sampling resolution of about 60 km. Then, from October 1983 to July 1984, the twin Soviet probes VENERA 15 and VENERA 16 surveyed the planet and mapped essentially the north pole area covering approximately 25% of the surface from 30°N to 88°N. The resolution of the reflectivity images ranges from 1 to 4 km and the topographic precision was 50 m with a sampling resolution of about 8 km. The last global data from the surface of Venus were obtained by the NASA MAGELLAN Orbiter. The insertion of the probe into the mapping orbit took place on 10 August 1990 and the formal mapping of the surface began on 1 September 1990. These operations, divided in four observation cycles, lasted until 14 October 1994 when the probe was lost. The coverage of the surface was almost complete. The precision of the altimetric data is below 50 m at a sampling resolution of the order of 10 km. The resolution of the reflectivity images is of the order of 75 m.

Infrared observations of Venus have been made from the ground and during the flyby of Venus by two probes. The first one was GALILEO during its travel to Jupiter on 10 February 1990 and the second occured very recently with the CASSINI/HUYGENS probe on 24 June 1999 during its travel to Saturn. These two probes have infrared spectrometers on board (NIMS on board Galileo and VIMS on board Cassini). The surface was detected on the nightside of Venus by its thermal emission. These observations show that the surface temperature is in equilibrium with the atmosphere at the same altitude (see VENUS: ATMOSPHERE).

Local observations

All available on-ground local observations and measurements come from the various Soviet Venera/VEGA landers. These probes have made images of the ground surrounding them and/or composition analysis of the surface. The first of these landers was Venera 8 that landed in 1972 and gave the first natural radioactive element composition of the surface. Then three sets of twin probes reached the surface. The first pair of landers were Venera 9 and 10 that made images of the surface and chemical analyses in October 1975. They were followed seven years later by Venera 13 (1 March 1982) and Venera 14 (5 March 1982) landers that made color images of the surrounding surface and also surface composition analyses. Finally the Vega 1 and Vega 2 probes in 1984 were able to analyse the soil composition.

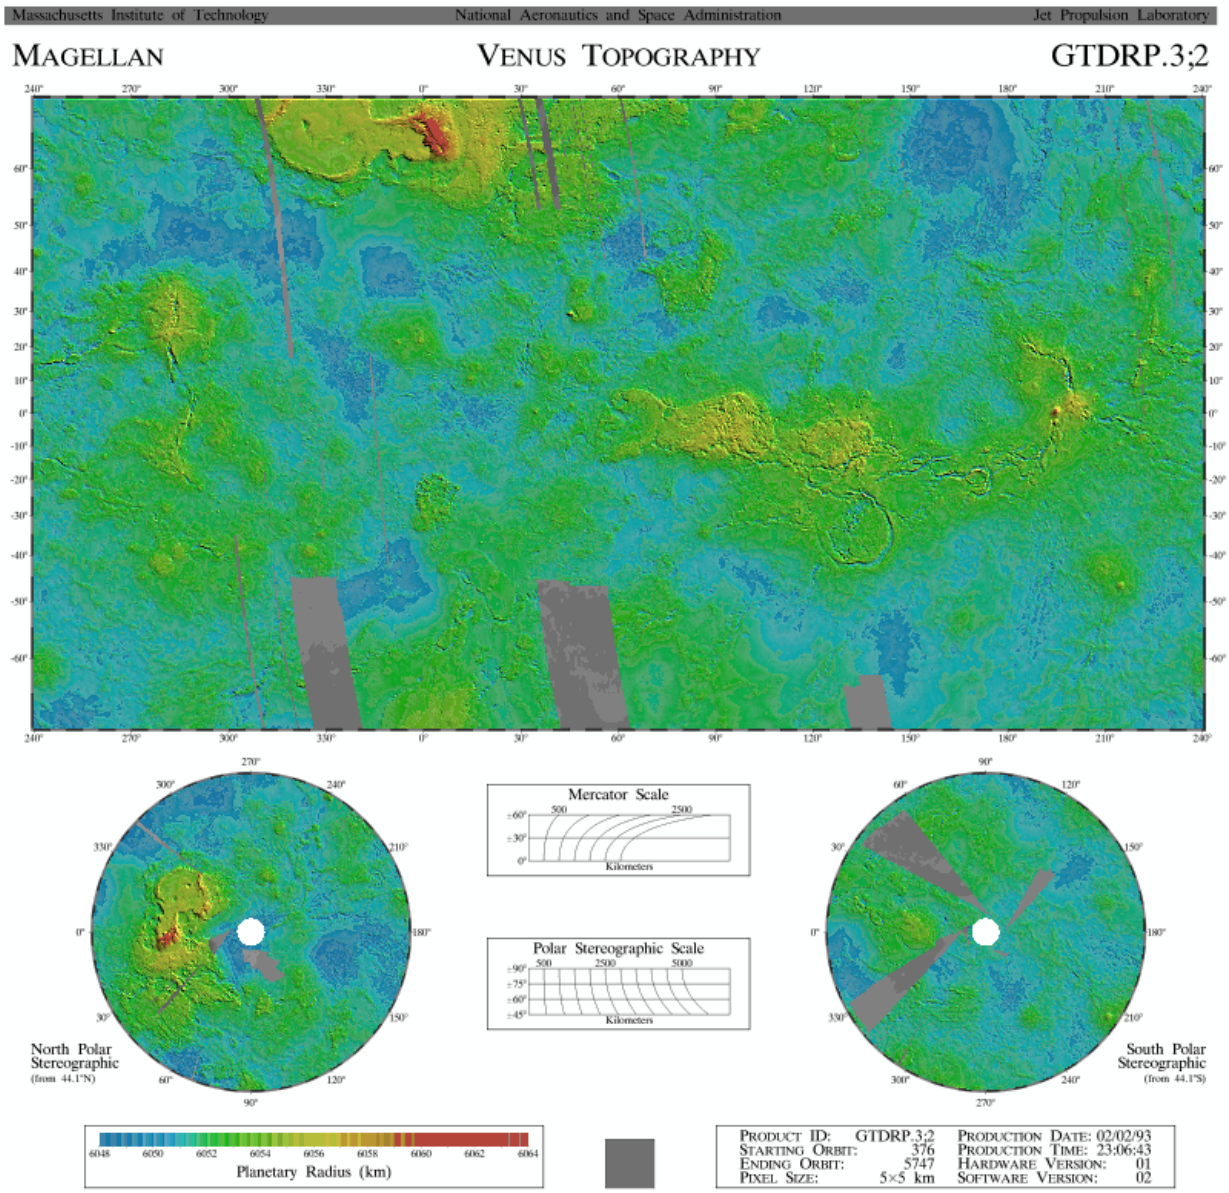

Figure 1. Topographic map of Venus. The highland at the equator is Aphrodite Terra and the highland at the north is Ishtar Terra.

Global topography

Although Venus, like most of the TERRESTRIAL PLANETS, can be divided into two broad physiographic regions, highlands and lowlands, its hypsometric distribution is unimodal, unlike that of the Earth (bimodal) or Mars (trimodal) and over 80% of the Venusian surface lies within 1 km of the mean radius of 6051.84 km (figure 1). The mean slopes on Venus are of the order of 1° but average kilometer-scale slopes greater than 30° are not uncommon.

Highlands

- Regio (regiones, pl.) are topographically high regions, often hosting large shield volcanoes.
- Terra (terrae, pl.) cover vast areas and have variable topographic relief, as continents do on Earth.
- Planum (plana, pl.). Lakshmi Planum is the only planum recognized on Venus. It is a 3–4 km high plateau, bordered by mountainous ridges.

There are four highland areas on Venus: (1) ISHTAR TERRA in the north, (2) LADA TERRA in the south, (3) APHRODITE TERRA in the equatorial zone east of the prime meridian and (4) the last area is defined by BETA REGIO, Phoebe and Themis regiones distributed along roughly the 285° meridian.

Ishtar Terra comprises the high Lakshmi Planum plateau to the west and the extremely elevated region

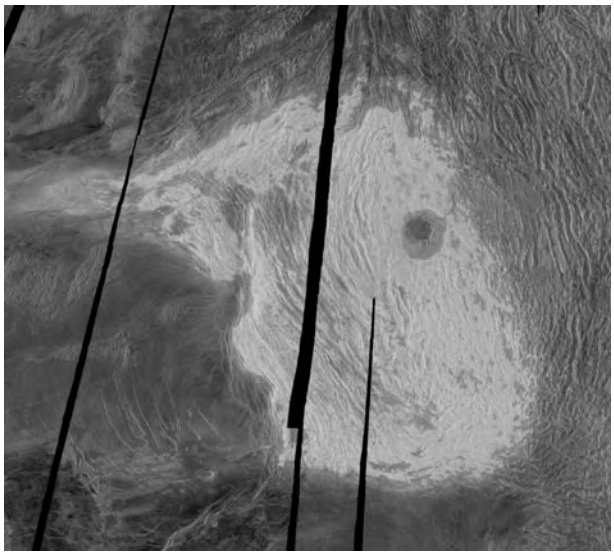

Figure 2. This Magellan full-resolution image shows Maxwell Montes, and is centered at 65°N latitude and 6°E longitude. Maxwell is the highest mountain on Venus, rising almost 12 km above mean planetary radius. The western slopes (on the left) are very steep, whereas the eastern slopes descend gradually into Fortuna Tessera. The broad ridges and valleys making up Maxwell and Fortuna suggest that the topography resulted from compression. Most of Maxwell Montes has a very bright radar return; such bright returns are common on Venus at high altitudes. This phenomenon is thought to result from the presence of a radar reflective mineral such as pyrite. Interestingly, the highest area on Maxwell is less bright than the surrounding slopes, suggesting that the phenomenon is limited to a particular elevation range. The pressure, temperature and chemistry of the atmosphere vary with altitude; the material responsible for the bright return is probably only stable in a particular range of atmospheric conditions and therefore a particular elevation range. The prominent circular feature in eastern Maxwell is Cleopatra. Cleopatra is a double-ring impact basin about 100 km in diameter and 2.5 km deep. A large amount of lava originating in Cleopatra flowed through this channel and filled valleys in Fortuna Tessera. Cleopatra is superimposed on the structures of Maxwell Montes and appears to be undeformed, indicating that Cleopatra is relatively young.

surrounding the Maxwell Montes that are, with their 12 km altitude, the highest topographic point on Venus (figure 2).

Lowlands

- Planitia (planitiae, pl.) are topographic low-lying regions, generally the most featureless on Venus in terms of tectonic and volcanic structures.

There are five lowlands areas in which lie other smaller highlands: (1) Atalanta Planitia at the north of Aphrodite Terra, (2) Aino Planitia and (3) Helen Planitia at the south of Aphrodite Terra, (4) Guinevere Planitia at the equator between Aphrodite Terra and Phoebe Regio and (5) Lavinia Planitia at the south of Guinevere Planitia. The small highlands are Alpha Regio (6°E, 25°S), Eistla Regio (39°E, 18°N), Bell Regio (49°E, 33°N) and Tellus Regio (82°E, 39°N).

The landscape of Venus

The landscape of Venus is characterized by some very particular and specific geomorphological and tectonic features that illustrate how Venus can be very different from the Earth and that can help to understand its geological history.

Volcanic features

Several types of volcanic flows and edifices are recognized. The presence of volcanic features on Venus suggest local magma sources at depth. The distribution of these features may provide clues about the crustal properties and thermal history of Venus. They can be divided into three groups according to their mean size. Brief characteristics are given for each below:

(i) Large volcanic forms (<100 km): large shield volcanoes are characterized by numerous lava flows radiating away from a central caldera. Many individual flows extend for hundreds of kilometers. Several of the 156 identified shields are located in topographically high regions (e.g. Gula and Sif Montes at Western Eistla Regio; Sapas, Maat and Ozza Montes at Alta Regio) reaching elevations as high as 3–5 km above the surrounding area.

(ii) Intermediate-sized volcanic forms (20–100 km):

- Anemones: a type of volcanic edifice characterized by flows radiating outward, often in bilateral fashion from a central graben or fissure. They are relatively rare; only 25 have been identified. Anemones are typically 30–40 by 40–60 km in dimension.
- Ticks are volcanic domes, so named because of their appearance in radar images. They have flat or depressed circular domes about 25 km in diameter and are flanked by strongly defined radial ridges and troughs. At one end, the tick edifice may exhibit signs of a collapsed graben with extensive fault scarps. Occasionally, flows originating from the small central calderas appear to be directed outward along the radial fault-valleys. About 50 have been identified.
- Steep-sided domes, commonly referred to as pancake domes: these volcanic domes have well-defined circular outlines and are characterized by radial fractures near the steep perimeter, radial and concentric fracturing on the flat interior and small summit calderas near the center. Over 150 have been recognized, very often in groups, sometimes overlapping one another.
- Calderas and paterae are volcanic depressions bounded by arcuate fault scarps and are the source area of numerous lava flows. 86 calderas have identified.

(iii) Small volcanic forms (>20 km) shield fields cover relatively large areas (average area 17 700 km^2) and are delimited by numerous, but small (typically 2–3 km across, but 6–12 km ones are not unusual) volcanic domes or vents. Some shield fields develop extensive flow fields surrounding the shield volcanoes whereas others are located within tectonic structures such as coronae or linear extensional zones. Overall, 556 shield fields have been recognized on Venus.

Tectonic features

Many features recognized from Magellan images are reminiscent of TECTONIC structures on Earth. Some of these features cover regions of thousands of square kilometers, whereas other features are narrow linear structures that appear to be related to fractures, grabens and perhaps dykes. A classification and nomenclature of Venusian physiographic features and how they may be related to tectonism has been made. Some of these features are described below.

(i) Large tectonic forms (100 to 1 000 km) are:

- Tessera (tesserae, pl.): a terrain network consisting of two or more directions of anastomosing linear ridges and troughs. They are tectonically complex terrains, thought to be largely compressional in origin and may represent the oldest part of the crust.
- Chasma (chasmate, pl.): a broad trench or linear zone consisting of a parallel arrangement of troughs or valleys bounded by fault scarps. These zones are interpreted to reflect extensional tectonics.
- Mons (montes, pl.): large highland provinces are termed montes (e.g. Maxwell Montes, Danu Montes, Akna Montes and Freyja Montes), descriptive of their mountain range-like appearance (figure 2).

(ii) Others features likely to be associated with volcanic and/or intrusive activity are:

- Corona (coronae, pl.): (mean diameter = 250 km) are large circular structures whose circumference is defined by an elevated ring-like zone consisting of compressional ridges and extensional troughs. The interior part often shows evidence of volcanic activity and early fracturing. Radial graben-like structures may extend beyond the outer diameter. Topographically, the interior may be raised or depressed relative to the surrounding terrain. Corona structures likely represent the surface expression of mantle upwelling. They range from 75 to over 2000 km across and occur in groups, in chains or as isolated structures. More than 360 have been recognized, of which about half have been formally assigned names (figure 3).

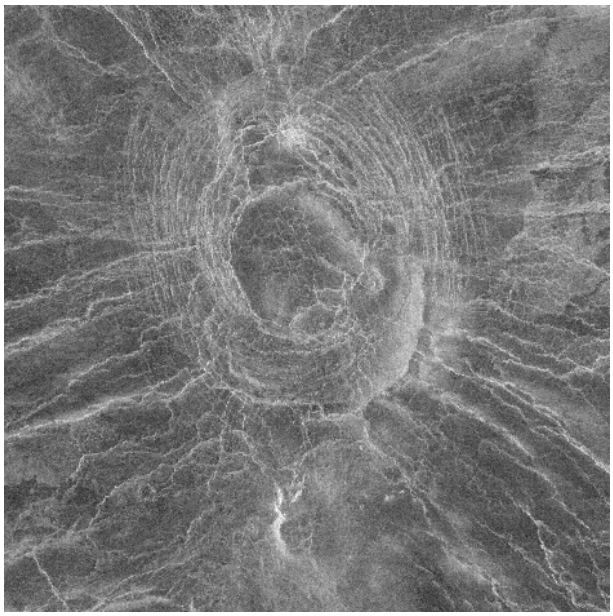

Figure 3. This region, roughly 100 km on a side, shows a gigantic structure known as a corona. Coronae are circular to elliptical features marked by a ring of concentric ridges. Such features are thought to be the result of hot rising bodies of magma that reach the crust. As hot material rises, it weakens the upper layers of the crust, causing the surface to dome upwards. Then as the region cools, the dome begins to subside. As the upper layers rise and fall, they are subjected to stresses that crack the surface, creating both circular and radial fractures. Magellan acquired this view of Venus during its first mapping cycle around the planet in 1990 and 1991.

- Arachnoid(s) (mean diameter = 115 km) are circular to elliptical structures that consist of a central dome or depression surrounded by an extensive network of radial and concentric linear features. These locally developed structures may represent the surface expression of faulting and dyke emplacement associated with magma injection at shallow depths. About 259 have been found on Venus.
- Nova (novae, pl.) (mean diameter = 190 km) are similar to arachnoids, but are dominated by radial structures. Novae are generally centered on a domal uplift and may possibly represent the early stages of corona formation. Over 50 have been identified.

Impact craters

There are 935 recognized impact CRATERS on Venus. About half the craters have been formally assigned names, the others remain unnamed. All have been named after famous women in history, but craters with diameters less than 20 km have been given female common names. Venusian craters range in size from 1.4 km in diameter to

280 km. Crater Mead is the largest impact crater identified on Venus.

In contrast to Mercury, Mars or the Moon, which are covered with thousands of craters that have accumulated over the last 4 to 4.5 billion years, Venus is scarred by curiously few. In fact the spatial distribution of craters is uniform (random and anticlustered) over the entire planet, suggesting that Venus experienced complete global resurfacing in the relatively recent (geologically speaking) past.

In the global resurfacing model, tectonic and volcanic activity affected the entire surface of Venus which obliterated the majority of (if not all) previous impact craters. An observation that lends support to the sudden arrest of these events is the fact that the majority of craters, 84%, do not show any signs of modification. This resurfacing activity is thought to have ceased between 300 to 800 million years ago. The uncertainty of the timing lies in the uncertainty of estimating the impact flux.

Craters on Venus are recognized by their expression on images and hence classified by their morphology. The high temperature of the Venusian surface (470 °C) and its thick atmosphere make Venusian impact morphology unique among planetary bodies in the solar system. Based on the development of crater floor structures and degree of circularity, a classification of simple craters and five types of complex crater into a six-fold scheme can be made.

- Structureless craters are simple craters where the internal floor is flat and featureless. The smallest craters are generally of this type.
- Central peak craters have a central uplift that rises above the crater floor. These craters range in size from 8 to 79 km, but are most commonly 16–32 km. Outlining rims are quite circular and often terraced.
- Double-ring craters are defined by an outer rim and a circular arrangement of inner peaks and ridges. These craters are typically greater than 40 km.
- Multiple-ring craters have two or more concentric ridge structures that rise above the crater floor. The largest craters on Venus, ranging from 86 to 280 km in diameter, are of this type.
- Irregular craters have non-circular rim outlines and structural disruptions to otherwise flat crater floors. Almost one-third of the craters on Venus are of this type, most of which are less than 16 km across.
- Multiple crater formation occurs when a falling body fragments into pieces. Each fragment creates a separate impact crater whose rim may overlap with adjacently formed craters. Individuals of this type are up to 44 km in diameter, but most are less than 11 km.

In general, small-diameter craters are flat-floored, have irregular outlines and may be part of a multiple impact event. Complex internal structures occur in large craters and tend to develop progressively as a central peak, a double ring, or a multiple ring, with increasing crater diameter.

Surface properties and composition

A somewhat unexpected finding in the Magellan images was the abundant wind streaks. More than 4000 wind streaks have been identified and this evidence of eolian activity is widespread and is particularly concentrated between 17°S and 30°S latitude and at 5°N–52°N on smooth plains. These wind streaks are generally oriented with the downwind direction towards the equator. This eolian activity is also demonstrated by parabolic crater deposits, made up of fine, centimeters thick debris distributed by high-speed zonal E–W winds. These observations are consistent with the radar signature of the surface that indicates that weathering, mass wasting and eolian activity operated continuously on deposits similar to lava flows. This activity confirms the aspect of the surface as it is known by the Venera lander images (figure 4). The reddish color of the images taken by the Venera 13 and Venera 14 landers also supports the volcanic origin of the surface which is confirmed by the chemical composition.

Our knowledge of the chemical composition of the surface of Venus comes from two types of experiment on board the seven Russian landers. These two methods are gamma spectroscopy and x-ray fluorescence spectrometry. The first one gives the contents of the radiogenic elements,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

Figure 4. Venera 14 lander images of the surface of Venus at 1°S, 310°E on 5 March 1982. The lander survived for 60 min. Both images show part of the lander at the bottom. This area is composed of flat basalt-like rocks, but little soil or fine-grained material, as was seen at other Venera lander sites. Near the center of the top image is a lens cover, and the bottom image shows a test arm.

uranium, thorium and potassium (table 1). The second one gives the contents of the major elements of the surface rocks (table 2).

Most of these analyses show a trace element and/or bulk chemistry typical of tholeitic basalts. Moreover, all the dominant type of terrain within the Venera/Vega landing sites is plains so that their measurements can be considered representative samples of the Venusian plains. Finally morphological observations of long and vast lava flows together with the results of the geochemical measurements show that the plains of the landing sites as well as the Venusian plains as a whole are predominantly the result of large basaltic volcanism. Two exceptions come from the data of Venera 8 and Venera 13. The gamma spectroscopic analysis at the Venera 8 landing site shows that the surface material contains relatively high amounts of K, U and Th (table 1). X-ray fluorescence analysis at the Venera 13 site shows that the bulk chemistry of the surface rocks is analogous to that of alkaline basalt. Its potassium content is indeed very similar to that of the Venera 8 site. For these two sites, where non-tholeitic composition of the surface material was identified, steep-sided domes have been found which are not present at the other sites. These particular morphological features, together with the fact that the Venera 8 and possibly Venera 13 material compositions are the combination of evolved igneous rocks and more mafic and primitive rocks, suggest that these rocks are the geochemical signature of the presence and involvement of material of continental crustal origin in their magma genesis. This raises the question about the presence or absence of continental-like crust on Venus, which remains an enigma.

Stratigraphic history

From the study of all these features and of their morphological and chronological relationships, a tentative geological history of Venus can be proposed, defining units of common ages, their formation and evolution through time as described by Basilevsky and Head (1998) (see figure 5).

The oldest unit, the Fortuna Group, is mainly composed of tessera terrains that cover about 8% of the Venusian surface. The morphology of this unit is dominated by intersecting systems of ridges and grooves of tectonic origin. This deformation does not extend into the surrounding plains that clearly embay the tessera. It is not clear if this group was formed in a very short time or if it is composed of various subunits of different ages. However, it is clear that all other units overlie or embay this group, making it the oldest recognized unit of Venus like the Precambrian basement of continents on Earth. Although this group may have formed at different ages, its heavy deformation seems to have spanned a relatively short period of time as suggested by the density of superposed impact craters that is approximately the same.

The next unit in chronological appearance is called the Guinevere Supergroup. It represents an assemblage of plains-forming units and consists of four groups separated from one another and from the underlying Fortuna Group by episodes of tectonic deformation.

The first unit consisting of material of densely fractured plains is called the Sigrun Group and covers 3% of the surface of Venus. It appears as uncovered terrains by the younger plains and is deformed by densely spaced swarms of faults usually subparallel to each other. The material composing this unit appears to be primarily plains that were emplaced as floods of lavas.

The second group, called the Lavinia Group, is represented by the materials of fractured and ridged plains and covers about 3% of the surface. The ridges are sometimes clustered forming ridge belts. They appear

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

generally as elongated islands among the younger plains but embay the tessera and the Sigrun Group. The Lavinia Group material, as the Sigrun Group, was also primarily emplaced as lava floods (figure 5(*a*)).

The third group consists of materials of shield plains and plains with wrinkle ridges. Together this group, called the Rusalka Group, occupies 70–75% of the surface of Venus. The wrinkle ridges plains dominate among this group and represent 60–65% of the total surface. A characteristic of these plains is the presence of wrinkle ridges, typically 1 km wide, that often form a network with a dominant trend. Usually subunits can be recognized in this group because they are deformed by a single ridge network, thus separating them all from the younger stratigraphic units. The youngest of these subunits form extended flow-like features. This observation and the *in situ* geochemical measurements made by the Venera 9, 10 and Vega 1, 2 landers suggest that these plains formed by extended floods of mafic lavas. The shield plains is the second component of the Rusalka group. It is represented by materials of plains formed by clustered and coalescing sloping shields of volcanic origin. These plains occupy 10% of the surface of Venus and are usually embayed by the wrinkle ridge plains that appear consequently younger. The volcanic shields, on the basis of their gentle slopes, are made by lavas composed of alkaline basalts or even more differentiated material such as andesite as shown by the Venera 8 analyses.

The last group of the Guinevere Supergroup is mostly made of the materials of lobate and smooth plains undeformed by wrinkle ridges. This unit covers 10–15% of Venus and is called the Alta Group. It overlies and embays all the already described units. Most of the Alta Group materials are associated with rift zones occurring in the form of large, gently sloping volcanic edifices. Some materials of this group are associated with coronae, forming lava flows aprons around them. Their morphology as well as their geochemical composition given by Venera 14 suggest that they also are mafic lavas.

The last and youngest group, the Aurelia Group, is represented by the materials of radar-dark parabolas associated with the youngest impact craters as well with the eolian patches and streaks.

Absolute age estimates

The duration of the morphologically distinguishable part of the geological history of Venus is estimated on the basis of impact crater densities. The average age of the surface of Venus is estimated to vary between 300 and 500 million years, for the lower bound, up to 800 million years for the upper bound. In terms of this average age T, the age of the oldest group represented by the tessera is estimated to be about $1.4T$. Then, the average age T of the surface of Venus is apparently a good estimate of the age of the Rusalkian Group. This means that the total duration of the Sigrunian, Lavinian and Rusalkian group is of the order of 0.2–$0.3T$ that is, approximately a few tens of millions of years to about one hundred million years. Finally, the upper boundary of the Atlian time (that is, the lower boundary of the Aurelian period) was estimated from the proportion of craters with radar-dark parabolas to be about $0.1T$ prior to the present (figure 5(*a*)).

Geological history of Venus

The history of Venus as recorded on its surface represents only the last 10–20% of the total history of the planet because the morphological signatures of the terrains before those of the Fortuna Group were not preserved. The beginning of this part of the history of Venus is characterized by intensive tectonic deformation on a global scale which formed the tessera terrains. Early stages of this deformation were clearly compressional and later changed into extensional. Termination of the compression stage is estimated to have occurred at about time $1.4T$, while the extensional stage lasted for another 0.1–$0.2T$. Numerous internal dynamical processes have been proposed to account for the tessera-forming deformation sequence; from chemical instabilities causing mantle overturn, an oscillatory convective behavior of the mantle or catastrophic avalanche within the mantle due to the presence of high-pressure phase transitions. These hypotheses raise the question of whether the large currently preserved tessera blocks might represent relicts of downwelling or upwelling. Anyway, this intensive tectonism was accompanied by volcanic activity so that the emplacement of tessera-forming material and its deformation into tessera terrain are the major geological events of Fortunian time (figure 5(*a*)).

After tessera formation, several stages of extensive volcanism occurred that buried vast areas of the tessera and formed the regional plains of Sigrunian, Lavinian and Rusalkian ages. The combined duration of the emplacement of these plains is estimated to be 0.2–$0.3T$. Plain forming of all these groups is separated by episodes of tectonic activity that occurred generally synchronously in different areas of Venus. These episodes are characterized by the dominance of compression, then tension, then again compression, and finally tension. The last globally distributed tectonic episode, extensive wrinkle ridging, happened at about time T and marked the transition to the present stage of the history of Venus, which is dominated by regional rifting and its local associated volcanism in the form of large shield volcanoes. The majority of this stage is represented by the Atlian period, which appears to have lasted until $0.1T$ from the present. This period is thus the longest in duration among all the other units, although its resulting tectonic and volcanic features and deposits represent only 10–20% of the surface of Venus. The last period of the history of Venus is the Aurelian period and is characterized by a certain level of reworking of the surface by eolian processes. From the point of view of volcanic and tectonic processes, it represents simply the continuation of the Atlian period so that Venus may be today already endogenically active at a low level (figure 5(*b*)).

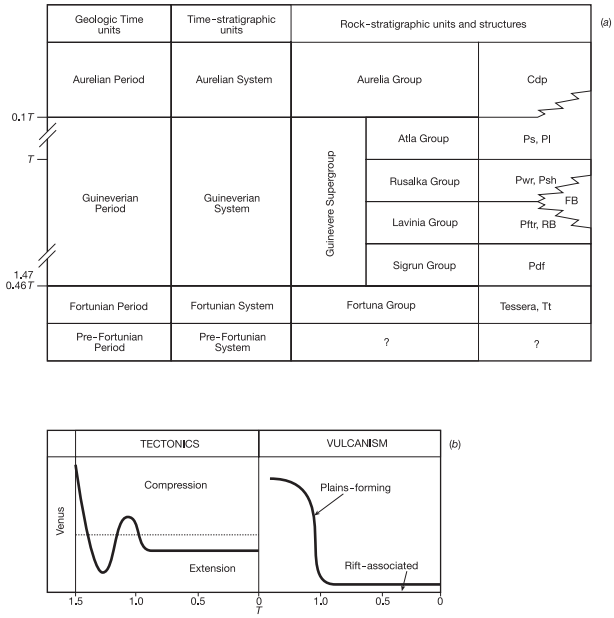

Figure 5. (*a*) Venus stratigraphic units following Basilevsky and Head (1988) (Tt: tessera terrains; Pdf: densely fractured plains; Pfr: fractured and ridged plains; RB: ridge belts; FB: fracture belts; Pwr: wrinkle ridge plains; Psh: plains with shield; Ps: smooth plains; Pl: lobate plains; Cdp: dark parabola craters). (*b*) Summary of the geological history of Venus. The tectonic is dominated by the succession of compression–tension cycles and the volcanism, intense at the beginning, decreases and changes in style with time (Basilevsky and Head 1998). T, the average age of the surface of Venus, is of the order of 300–500 million years or possibly up to about 800 million years.

In summary, the observable part of the history of Venus is characterized by two key points that stand in contrast to the comparable period of Earth history when global geodynamical processes are dominated by plate tectonics.

(a) Venus shows no signature of plate tectonics. Instead, its global tectonic environment is characterized by two successive compression–tension cycles with the magnitude of the deformation and strain rate declining with time.
(b) During the first cycle, plains-forming volcanism occurred at a rate comparable to terrestrial volcanism but in a non-plate tectonic style, and then during the second cycle Venus was dominated by a rift-associated volcanism emplaced at a very low production rate comparable with that of today's intraplate volcanism.

The surface features, structures and composition illustrate the distinctive difference between the recent history of Venus and the Earth that are in other ways so similar.

Very Large Array, National Radio Astronomy Observatory

The Very Large Array (VLA), 80 km west of Socorro, NM, is one of the world's premier radio-astronomy facilities, offering researchers a unique combination of resolving power, sensitivity and observational flexibility. Dedicated in 1980, the VLA includes 27 25 m diameter dish antennas, arranged in a 'Y' pattern, that work together as a single aperture-synthesis interferometric imaging system.

A facility of the US National Science Foundation, the VLA is open for use by all scientists on a peer-reviewed basis. Capable of observing at frequencies from 74 MHz to 50 GHz (non-continuous), and with antennas deployed through a 16 month cycle of four standard configurations, the VLA provides resolution ranging from 15 arcmin to 0.05 arcsec.

The VLA's versatility has allowed it to serve a wide range of research specialties, including planetary, solar, stellar and galactic astronomy as well as cosmology. It has made important contributions to the study of both galactic and extragalactic relativistic jets; the Milky Way's central region; galactic structure, dynamics and evolution; supernova remnants; and transient events such as supernovae and gamma ray bursters.

Very-high-energy Gamma-ray Sources

Gamma-ray photons at TeV energies have been observed in recent years from a special class of active galactic nuclei, the so-called BLAZARS. The maximum photon energy observed is now approaching energies beyond 10 TeV, opening up new windows into the high-energy universe.

The basic concept in our present day understanding of ACTIVE GALACTIC NUCLEI is the existence of a central BLACK HOLE (our Galaxy is now well established to harbor one of $\sim 2.5 \times 10^6$ solar masses (Genzel *et al* 1997)) with a surrounding ACCRETION DISK. Perpendicular to the inner accretion disk is a stream of high-velocity gas, commonly referred to as a jet; one expects jets on both sides. The material in this jet is usually moving at very near the speed of light. In addition, this basic picture appears to hold quite well for solar mass black hole systems such as some compact binary stars in our Galaxy, as well as for the most powerful quasars we know, with black hole masses of the order of 10^{10} solar masses.

From Hubble Space Telescope observations we have also learned that these massive black holes always sit in the dynamical center of their host galaxies. The spheroidal distribution of older stars within these galaxies has a mass which appears to be approximately proportional to the mass of the central black hole, with a factor of order 300. This can be readily understood in an accretion disk scenario by modelling the entire galaxy as a system of accreting gas, out of which stars are formed and which feeds the budding black hole at its very center. Mergers of galaxies then turn these disks of stars into a more spherical distribution (Faber *et al* 1997, Wang and Biermann 1998).

The radio emission from the environment of these black holes and their associated jets is usually dominated by non-thermal emission from the jet, most often synchrotron emission from the gyrating motion of highly energetic electrons/positrons in a magnetic field. This emission process is accompanied by absorption, and so often synchrotron self-absorption becomes important. In the overall radio emission from the various segments of the jet this leads to an approximately flat spectrum, where the flux density (energy per bandwidth per second received in a unit telescope area) is approximately constant with frequency. A survey of the data shows that such flat spectrum radio sources are almost always variable, and show signs of bulk relativistic motion along the jet.

The power from active galactic nuclei ranges from under 10^{38} erg s^{-1} to over 10^{47} erg s^{-1} (1 erg $= 10^{-7}$ J). The source sizes, best measured by intercontinental radio interferometry, can extend from smaller than the solar system to many millions of light years. Their emission in the electromagnetic spectrum has been observed from around 10 MHz in the radio to a photon energy beyond order of 10 TeV (1 TeV $= 10^{12}$ eV $= 1.6$ erg $= 1.6 \times 10^{-7}$ J).

Basic concepts

We measure motions close to the speed of light in terms of the Lorentz factor γ, where

$$\text{Lorentz factor } \gamma = \frac{1}{\sqrt{1-\beta^2}}. \qquad (1)$$

The relative speed is $\beta = v/c$, where v is the velocity of the particle or material such as gas in a jet under consideration, and c is the speed of light.

We call the motion of matter relativistic, when γ is much larger than unity. Since the total energy E of a moving particle is given by $E = \gamma mc^2$, where m is the rest mass of the particle, the total energy can be very large. The largest particle energies directly observed are 3×10^{20} eV, which corresponds for protons to a Lorentz factor of 3×10^{11}. The motions of jets in active galactic nuclei can often be characterized by a bulk Lorentz factor of order 10. From the electromagnetic emission from these jets, we can infer Lorentz factors of electrons moving around inside the jet in its frame of reference of order 10^6 and lower.

We observe the electromagnetic emission from highly relativistic electrons, and possibly protons, from these jets at all wavelengths, and interpret the radiation at TeV energies also as emission from a relativistic jet. The principal source of this emission can be synchrotron emission, due to the gyrating motion of highly relativistic electrons in a magnetic field. It can also be inverse Compton emission, from collisions between relativistic electrons and photons. Obviously, at high photon energies approaching or exceeding 10^9 (1 GeV), it can also for instance derive from π^0 decay following hadronic interactions.

Hadronic interactions are interactions between nuclei or between other particles where pions (or at extreme energies nuclei) are created. Since pions have a large rest mass, and in turn decay into photons or muons and neutrinos, hadronic interactions are usually heralded by the emission of neutrinos.

Observational techniques

At TeV energies photons are observed on Earth with Cerenkov telescopes. These telescopes use the Cerenkov light emitted from the products of the shower maximum produced by interactions of the incoming primary particle, to determine its energy and direction. Since the overwhelming number of all primaries are directional randomly distributed charged nuclei, the intrinsic properties of photon and hadron initiated air showers (see COSMIC RAYS: EXTENSIVE AIR SHOWERS) may be also used for a separation between photons and hadrons (see Gaisser (1990) and reviews by Weekes (1996), Cawley and Weekes (1996) and Weekes *et al* (1997)).

Looking into the air shower one sees an image, which is rather different for hadronic showers and purely electromagnetic showers. Hadronic showers produce an image which is very irregular in its appearance,

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

while electromagnetic showers, initiated by a high-energy photon, give an elliptic image, which points towards the source on the sky. This analysis was originally developed by M Hillas of Leeds, and then evolved into a technique by T C Weekes, of Tucson, at the Whipple telescope (in the mountains of Arizona, USA).

There are internationally many telescopes using this technique, with one of the most active telescope arrays being HEGRA, on La Palma in the Canary Islands. There are further such telescopes in many countries now, such as in Australia, France, India, Russia, South Africa, Ukraine and USA (Meyer 1997, Ong 1998). Table 1 lists some of the major telescopes already in operation.

The acceptance of a large initial detectable photon energy is a strong function of the zenith angle of the observation, and one needs large zenith angles to reach beyond 10 TeV.

Observations

These observations started in 1992 with the first successful detection of Mrk421 by the Whipple observatory (Punch *et al* 1992).

There are now several blazars, which have been observed at such energies, with the most observations being taken of the objects Markarian 421 and Markarian 501, originally discovered by the Armenian astronomer B E Markarian. TeV energies means a factor of 1000 higher than the photon energy (1 GeV $= 10^9$ eV) at which a much larger class of blazars have been observed with the EGRET instrument onboard the COMPTON GAMMA RAY OBSERVATORY satellite (Mattox *et al* 1997). But all these blazars, whether seen only at GeV energies or at TeV energies, have common properties: all of them have a flat radio spectrum in the GHz range, are variable at almost all frequencies observed, and their radiation is interpreted as emission from a relativistic jet. In the case of the TeV blazars, their emission appears to be the greatest at these energies, far greater than at any other wavelength observed (Aharonian *et al* 1997, Bradbury *et al* 1997, Funk *et al* 1998, Hayashida *et al* 1998, Krennrich *et al* 1997, Zweerink *et al* 1997).

The observations now show that the spectral shape is variable, and occasionally extends to the edge of what is observable, suggesting that perhaps the emission continues to many 10 TeV. Some of the time the spectrum is flat, which means that the energy output per logarithmic photon energy interval is constant with energy. The variability time scale is as short as can be detected with the photon counting statistics, at a few hours or less.

Figure 1 shows the spectrum of Mkn501 measured by HEGRA. The work of Aharonian *et al* (1999a) shows that the spectrum continues without an obvious break to 24 TeV.

Physics

These observations are interesting in their own right: the Big Bang produced a bath of microwave background radiation as a remnant of its early hot phase, which can be characterized by a temperature of 2.73 K, based on COBE observations (Fixsen *et al* 1996). Early galaxy star formation extended the background radiation from dust emission around young stars to the far-infrared. Encounters of TeV photons with this microwave and far-infrared background produces electron–positron pairs, which translates to an effective absorption. Therefore observing a source at multiples of TeV energy gives us information about the far-infrared background at wavelengths otherwise nearly inaccessible. Interestingly, early models for galaxy formation in the universe exceeded the level required by the gamma-ray observations by a large margin. The gamma-ray data are still pushing the envelope lower for the possible level of far-infrared background radiation. Therefore these gamma-ray observations provide one of the most stringent limits known for the violent early phases of the universe (Malkan and Stecker 1998, Mannheim 1998, Stanev and Franchescini 1998).

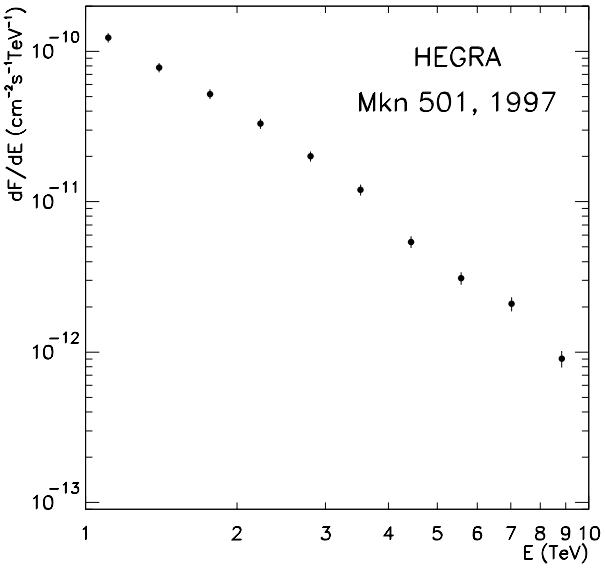

Figure 1. The spectrum of MKn501 as measured by HEGRA (Aharonian *et al* 1999b).

There are two main interpretations proposed for the physical process of the TeV gamma-ray emission itself, a leptonic and a hadronic process (Mannheim 1996).

The leptonic process proposed is a collision between a very energetic (and highly relativistic) electron and a photon from its surroundings either outside the jet, or inside the jet. In such a model electrons are presumed to be accelerated, all the while undergoing losses; this implies one stringent limit to their maximum energy, which leads to a maximum energy of any photon with which the electrons interact. This encounter, called the inverse Compton process, boosts the energy of the photon to much higher energies. In such a picture the maximum photon energy is then limited by the maximum energy the electron could have, and by the kinematics of the

collision. In standard models this leads to a limitation of the maximum photon energy to about 10 TeV.

A hadronic process can easily produce photons of much higher energy, by starting with energetic protons, which can clearly produce very energetic photons through proton–photon or proton–proton encounters and subsequent decay of a pion produced in the interaction. We observe high-energy particles directly from outside the Galaxy with energies up to several 10^{20} eV; since the gyration motion of such particles—if they are protons—is larger than the size of the Galaxy, they must come from outside, as argued early by Cocconi (1956). Also, the interaction of these high-energy particles with the microwave background ought to limit their energy upon arrival at Earth to less than 5×10^{19} eV, if they are protons; this expected cut-off is called the Greisen–Zatsepin–Kuzmin cut-off. It is not observed. We are still trying to identify the sources for particles at these extreme energies. If these active galactic nuclei could be shown to require protons at extreme energies, then we would have a very good candidate class. The experiments AGASA in Japan, HIRES in the US, and in the future AUGER in Argentina, are looking for more events at these extreme energies, to beyond 10^{21} eV (Biermann 1997).

We also expect TeV photon emission from the interaction of the known COSMIC RAY population (Berezinsky *et al* 1990, Wiebel-Sooth and Biermann 1999) in the Galaxy with the interstellar medium (Hunter *et al* 1997); since the cosmic ray spectrum of probable Galactic sources extends to 3×10^{18} eV, very high photon energies are expected from the decay of pions resulting from nucleus–proton encounters. Since the cosmic ray population is likely to be stronger in the galactic center region, we expect the as yet unobserved TeV emission to peak at the galactic center.

There is another class of sources for which TeV photons are expected to be detected at some point in the future: the now famous gamma-ray bursts (GRBs; see also GAMMA-RAY ASTRONOMY). GRBs are characterized by a sudden outburst of gamma-ray photons at typical energies of tens of keV to MeV, occasionally to GeV. The time scale of the emission is a few seconds, with substructure down to milliseconds. The time-integrated spectrum can be approximated by two power laws which break around 150 keV, suggesting a non-thermal process just as in active galactic nuclei jets. These GRBs are now known to be at cosmological distances (Metzger *et al* 1997), and thus require enormous powers to be released; it is still unknown what physical picture can explain all these features.

One immediate and clear consequence of the hadronic picture is the emergence of a cosmological neutrino background at high neutrino energies. This neutrino background would be much stronger at high energies than both the atmospheric neutrinos (which have now been used to present impressive evidence for neutrino oscillations by the Super-Kamiokande experiment), and also higher than the Galactic neutrino background, from p–p interactions of cosmic rays in the Galaxy (which in turn can be estimated from the observed GeV gamma-ray spectrum). There is currently an experiment at the South Pole, AMANDA, which hopes to detect this expected cosmological neutrino background.

Similarly a gamma-ray background is expected, which leads to another implicit use of those TeV gamma-ray data: what fraction of the diffuse gamma-ray background is due to active galactic nuclei such as blazars, and what fraction, if any, is left to be derived from different physics? Standard BIG BANG THEORY predicts ubiquituous relics, among them topological defects, which can decay into particles of the order of 10^{24} eV in most versions of the theory, which in turn decay via a cascade into protons, neutrinos and gamma rays, thus producing a truely diffuse gamma-ray background (Sigl *et al* 1995). If we could find an upper limit to the GeV and TeV contribution from the decay of topological defects, it would give a major constraint to particle physics near the energy scale of GRAND UNIFIED THEORIES for particles (GUTs).

Once we have thus identified a class of sources responsible for very-high-energy protons, possibly observable in high energy photons following interactions, and also other high-energy particles, then these accelerators in the cosmos and their environment provide us with tools—albeit very distant tools—to do very-high-energy physics at energies far beyond any physicist's dream.

Vesta

Vesta, with a mean diameter of 529 km, is the third largest main-belt ASTEROID and was the fourth asteroid to be discovered. It was found in 1807 by the German Astronomer HEINRICH OLBERS and named after the goddess of fire and the hearth in the Roman mythology. Vesta is the sole 'intact' asteroid that may have undergone heating at temperatures able to produce a complete planetary-type DIFFERENTIATION (when the heaviest element sank to the core of the asteroid while lighter minerals remained near the surface). Telescopic observations at high angular resolution, either from space or from the ground, can now provide images of Vesta's surface that help to better understand its formation and collisional history. Such images show that Vesta has undergone a large impact event, 4.5 billion years ago. This discovery supports the idea that Vesta is the parent body of a group of small Vesta-like asteroids and possibly the source of a particular type of METEORITES (the basaltic achondrite meteorites) collected on Earth. Although space agencies have not yet selected a large main-belt asteroid as primary target for a robotic mission, Vesta is considered an excellent candidate for future *in situ* exploration of the ASTEROID BELT.

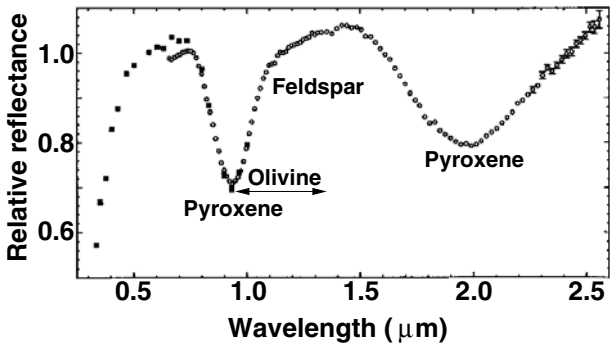

Figure 1. Mean reflectance spectrum of Vesta's surface at visible and near-infrared wavelengths. The deflections from the continuum are attributed to pyroxene and feldspar minerals. Olivine is also present on Vesta but locally only, and its absorption band is not visible in this rotationally averaged spectrum. Pyroxene, feldspar and olivine are characteristic of magmatic material. Their presence on Vesta is the signature of the high temperature it has undergone. Therefore, complete—or partial—melting occurred on Vesta, which is the only large differentiated asteroid that has escaped catastrophic and fully destructive collisions with other bodies of the asteroids' main belt. Spectrum from Gaffey (1997).

Surface properties

About every 18 months, Vesta is at OPPOSITION. Because its surface is made of high-ALBEDO material (table 1), the asteroid can be, at that time, visible with a naked eye (its visible magnitude becomes close to $6th$). Early photometric measurements made by Bobrovnikoff in 1929 showed that the surface of Vesta reflects irregularly the solar flux over a rotation period (∼5.34 h). These brightness changes could be more easily explained by strong albedo variations over its surface than through effects purely induced by an irregular shape. The particularity of its surface properties was confirmed in the 1970s when McCord *et al* obtained the first spectra of Vesta at visible wavelengths. They attributed a strong absorption band centered at 0.93 μm to the electronic transitions on the M_2 site of a magnesian pyroxene, transitions characteristic of magmatic minerals. The nature of its basaltic surface was confirmed soon after with the detection of the second absorption band of pyroxene near 2.0 μm. Figure 1 shows an averaged reflection spectrum of Vesta at visible and near-infrared wavelengths. In addition to the 1.0 μm and 2.0 μm bands attributed to pyroxene, a wide absorption band, also diagnostic of basaltic material, is visible between 1.1 μm and 1.4 μm and is produced by the presence of feldspar on Vesta. The strength of these bands varies across the surface, depending on whether the material has been excavated from underneath the crust by impactors or is a relic of the original eucritic layer. When compared with the spectra of other asteroid classes, the depth of the absorption bands displayed in the reflection spectrum of Vesta is among the strongest. Vesta has undergone powerful but localized impacts in its history that have preserved part of its primordial crust. As a result of these impacts, the variegated surface of Vesta produces strong features in the asteroid's lightcurve.

Table 1. Vesta's ID card.

Mean diameter	529 km [a]
Density	3.5 g cm^{-3} [a]
Rotation period	5.34 h [b]
Semimajor axis	2.362 AU
Orbital period	3.63 yr
Orbital eccentricity	0.097
Orbital inclination	7.14°
Pole coordinates	$RA_{2000} = 301°$, $DE_{2000} = 41°$ [a]
Asteroid type	V
Albedo	0.423 [c]
Composition	Pyroxene, feldspar, olivine

Link to HED meteorites

The distribution of minor planets as a function of their heliocentric distance is such that, the further from the Sun, the more primitive are the asteroids. All asteroids having surface properties characteristic of magmatic material are concentrated at the inner edge of the belt. Asteroids of types A (olivine + metal), M (metal), R (iron-poor pyroxene + olivine) or V (pyroxene–plagioclase, diogenite) can be found up to 3.2 AU from our star. Vesta's eucritic crust is nearly intact and is typical of a differentiated object that has undergone thermal heating at temperatures above 1000 K. The source of this heating is

Dirac House, Temple Back, Bristol, BS1 6BE, UK

still not certain but the actual adopted theories implicate electrical heating induced during the early T Tauri phase of the Sun or decay of long-lived radionuclides. Basaltic ACHONDRITE (or HED, for howardite, eucrite, diogenite) meteorites have similar composition to Vesta: the eucrites display the pyroxene absorptions as well as the weaker band of feldspar while diogenites are pyroxene rich and do not display the feldspar feature. Because of the similarity of their spectra, Vesta is suspected to be the parent body of the HED meteorites. Among the population of differentiated asteroid, Vesta, with a semimajor axis of 2.36 AU, does not occupy a remarkable position that could provide a significant flux of meteorites to Earth. Delivering pieces of Vesta to Earth would require some very energetic impacts that could produce fragments with velocities of the order of $\sim$1000 m s^{-1}. Only with such a kinetic energy could the fragments reach the nearest resonance zone (3:1 resonance with Jupiter) and be ejected towards inner regions of the solar system, and, for some of them, into Earth-crossing orbits. Binzel and Xu discovered in 1993 a family of small Vesta-like asteroids extending from the secular resonance ν_6 ($a = 2.18$ AU) to the 3:1 resonance with Jupiter (2.5 AU). Their visible spectrum displays the 0.9 μm absorption band which is also present in the spectrum of Vesta, eucrites and diogenites. More recent observations with the HUBBLE SPACE TELESCOPE and ground-based telescopes equipped with ADAPTIVE OPTICS showed the presence of a large impact zone located near the Vesta south pole (figure 2). These observations support the big picture in which Vesta could be the source of the family of small Vesta-like asteroids and be the parent body of the HED meteorites.

Although the pieces of the puzzle fit together nicely, alternative solutions still exist. Indeed, Vesta is the only differentiated asteroid that has survived catastrophic collisions, but we know from spectroscopic studies that asteroids from class A represent the inner mantle of some differentiated asteroids now disrupted. Similarly, asteroids from class M could be fragments of the core of some fully differentiated asteroids while class R asteroids are likely to be the product of the disruption of a Vesta-like asteroid, exposing material from the mantle and outer crust. These three asteroid classes originate from Vesta-like asteroids that have been entirely disrupted by impactors and constitute an additional potential source of basaltic achondrite meterorites. Astronomers have found several Earth-approaching asteroids whose surface composition is similar to HED meteorites. In addition, measurements of the oxygen isotope ratios in HEDs match closely those found in stony-iron meteorites and sustain the possibility that the HEDs might come, in fact, from a completely disrupted parent body, more than originating from removal of the outer layers of Vesta.

Regardless of whether the HED meteorites come from Vesta itself or have been created by disruption of one or several Vesta-like asteroids, the undoubted point is that Vesta is unique as the sole 'intact' differentiated asteroid. This point alone provides strong constraints to the collisional history of the whole asteroid belt.

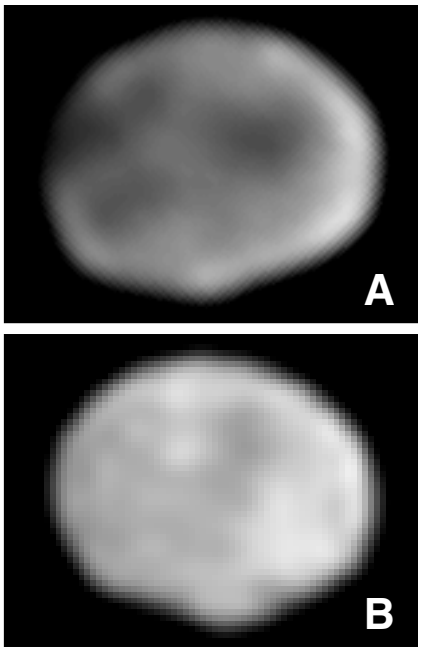

Figure 2. Asteroid Vesta imaged from the ground and space. (A) Image obtained at 0.83 μm from Mt Wilson Observatory on 14 June 1996 using the adaptive optics system on the 2.5 m telescope. A 20° phase angle is responsible for the strong increase in brightness of the right-hand side (eastern) limb of Vesta. The sub-Earth coordinates of Vesta are latitude = $-3°$ and longitude = 255° in this picture. (B) Image obtained by the Hubble Space Telescope and its visible camera WFPC2 on 6 May 1996 with a 5° phase angle. The central coordinates on Vesta correspond to latitude = $-9°$ and longitude = 12°. Both images are oriented so the spin axis is vertical, north pointing up. Note the strong albedo marks visible on Vesta that correspond to various geological units. These albedo changes are related to spatial variations in the surface composition as well as to the action of space weathering (aging process). A complete study at near-IR wavelengths is needed to fully understand the nature and history of these geological units. A simple picture would be to attribute the low albedo regions to old eucritic assemblages and the high albedo features to fresher material excavated from below the crust. The irregular shape of the south pole is believed to be the result of a major, but not fully destructive, impact that occurred on Vesta early in its history. These recent observations support the theory that HED meteorites and small Vesta-like asteroids might originate from such impact. Credit for (A): Christophe Dumas and Chris Shelton. Credit for (B): Alex Storrs (image processing) and NASA/STScI.

Surface mapping

Because of its early differentiation and volcanism, Vesta can be considered as the smallest terrestrial 'planet' of the solar system. Detailed mapping of its surface is important to understand how PLANETESIMALS accreted from the material that was present in the inner regions of the PROTOPLANETARY NEBULA and what endogenic and exogenic processes these planetesimals have undergone. Only a few techniques are currently available to return images with the required spatial resolution for mapping. The

most direct and expensive solution consists in obtaining *in situ* measurements of Vesta's surface from a spacecraft. At the present time, only three main-belt asteroids have been visited by a spacecraft: GALILEO flew over GASPRA and IDA (and discovered Ida's satellite named Dactyl) while *en route* to Jupiter, and the NEAR spacecraft visited Mathilde during its journey to a rendezvous with the near-Earth asteroid EROS. Ground-based optical observations were, until recently, limited in spatial resolution because of the deformations undergone by the wavefront of the light while traveling through atmospheric layers of different optical indices. For this reason astronomers used the Hubble Space Telescope to obtain the first resolved images of Vesta. However, new ground-based observational techniques, such as adaptive optics, can now measure the wavefront deformation and correct it in real time. Adaptive optics allows the large telescopes to image at angular resolution equivalent to their theoretical diffraction limit, providing performances at least comparable with HST. Other techniques such as speckle interferometry can provide diffraction-limited images but are still strongly limited to the observation of the brightest objects. Recent improvements in the sensitivity of radar detectors will allow radar observations of asteroids to be extended to the largest bodies in the main belt and their topography to be derived from Doppler-delay measurements.

The surface of Vesta is mostly a pyroxene–plagioclase assemblage with few regions where the excavated crust displays the feldspar-poor inner mantle material (diogenite). At a few locations, impacts occurred at energy sufficient to expose the deeper olivine-rich layer of the mantle. The core of Vesta is presumably made of metallic-rich material or even pure metal. In order to understand how Vesta differentiated, we need to measure the distribution of the diverse geological units over its surface. Depending on how Vesta melted, the distribution of diogenites would be different. In case of total melting of the asteroid, the diogenite-like layer would be confined underneath the eucritic crust while a partial melting would implicate a crust composition made of a mixture of feldspar-rich (plagioclase) and feldspar-poor (diogenites) units. Prior to the HST and adaptive optics observations, the first successful attempt to map the surface of Vesta from the ground was realized in 1981 by Gaffey using rotational spectroscopy. This technique consists in measuring the variation in depth and position of the bands with the rotational phase of the asteroid to derive the location and nature of the main geological units. Such measurement is better constrained in longitude than in latitude but a compositional map of Vesta could be derived and several geological units identified across Vesta. Thanks to the particular inclination of Vesta's rotation axis at the time it was observed, it was possible to locate several diogenite units near Vesta's south pole as well as one olivine-rich region near the equator. These units correspond certainly to a partial removal of the outer crust, or lava flows that transported diogenitic material to the surface through cracks in the mantle. The images recorded at various visible wavelengths by HST confirmed the existence of a large crater near the south pole. This feature is apparently the result of a large, but not entirely destructive, impact which had occurred on Vesta soon after its crust cooled down. Recent ground-based and HST results show an increase in the band depth of pyroxene at high southern latitude that could be explained by a local removal of the crust by the impactor to expose fresher material from the mantle. The family of small Vesta-like asteroids and HED meteorites could have originated from the EJECTA produced during this violent impact. The topology of the asteroid derived from the HST images agrees with this picture and the estimated mass excavated from Vesta during this impact could easily accommodate the formation of Vesta-like asteroids and HED meteorites. Complete mapping of Vesta at similar and even higher spatial resolution in the near-infrared (at a wavelength that provides a better diagnostic of the nature of the minerals) is currently under progress using HST and ground-based telescopes equipped with adaptive optics systems. These observations will bring some important insights to understanding the processes of planetary differentiation that occurred on Vesta and investigating the existing scenarios that link Vesta to the HED meteorites.

Viking Mission

The Viking mission was a spacecraft mission to MARS whose main purpose was to search for life. Four spacecraft were involved: two identical orbiter–lander pairs. Each pair was launched separately in the summer of 1975 and arrived at Mars the following year. At Mars the orbiters searched for safe and scientifically interesting sites. The landers were then targeted to those sites and conducted a variety of life detection experiments. The consensus view was that no compelling evidence for life was found (see also LIFE ON OTHER WORLDS).

The spacecraft

The Viking Orbiters (VO-1 and VO-2) were designed and built by the JET PROPULSION LABORATORY (figure 1). The orbiters were solar-powered, three-axis stabilized vehicles with substantial propulsive capability. The launch mass of the orbiters was over 2300 kg of which more than 1400 kg was fuel required for orbit insertion. The orbiter science payload was mounted on a moveable scan platform which provided both thermal control and pointing capability. In addition to communicating directly with Earth, the orbiters were capable of relaying data from the landers as well.

The Viking Landers (VL-1 and VL-2) were built under contract to Martin Marietta Aerospace Corporation (figure 2). The contract was managed by NASA's Langley Research Center. The landers housed the scientific instruments and were powered by radioisotope thermoelectric generators. Each lander had a sampling arm with a scoop for returning samples to selected instruments for analysis. Meteorology sensors were mounted on a boom, and a seismometer was mounted on the lander underside. The landers had a two-way communication link with Earth and a one-way (transmit) link with the orbiters. The mass of the landers was about 600 kg.

To avoid possible contamination from Earth organisms, the landers were heat sterilized and encapsulated in a bioshield. The encapsulated landers, including the entry system, had a total mass of almost 1200 kg. The landers were then mated to the orbiters and the combined craft placed in the shroud of a Titan III launch vehicle. The final launch mass of the orbiter–lander pair was 3530 kg.

Experiments

While the primary scientific objective was to search for life, other objectives were to image the surface and moons, determine the composition of the atmosphere and surface, monitor the weather and climate, and detect marsquakes. To meet these objectives, 13 investigations were conducted (table 1): three mapping experiments from orbit, an atmospheric investigation from the lander during entry, eight investigations on the surface and a radio science experiment.

The orbiter mapping experiments were carried out by three instruments: (1) a pair of high resolution vidicon cameras incorporated into a Visible Imaging Subsystem (VIS), (2) an Infrared Thermal Mapper (IRTM) to determine the thermal properties of the surface and atmosphere and (3) a Mars Atmospheric Water Detector (MAWD). Each of these instruments was mounted on the scan platform and aligned along a common axis to view the same area of the planet.

During the time the landers were traversing the atmosphere, an entry science investigation was conducted. This consisted of a retarding potential analyzer to measure the ion and electron abundances of the upper atmosphere, a mass spectrometer to measure neutral species and a three-axis accelerometer to measure the spacecraft deceleration history. Pressure and temperature were also measured (see also MARS: ATMOSPHERE).

The lander cameras were designed to characterize the local geology, look for macroscopic evidence of life and support the other lander experiments. The two cameras also provided a stereoscopic capability. Furthermore, by monitoring the brightness of the Sun and sky, the cameras could provide information on the opacity of the atmosphere.

The lander biology investigation consisted of three experiments. Each of these acquired small samples of Martian surface material and exposed them to substances of various kinds and then monitored the results. The Carbon Assimilation Experiment was designed to detect photosynthesis of organic compounds by introducing radioactively labeled CO and CO_2 gases incubated under Mars-like conditions. The Labeled Release Experiment sought to detect metabolic processes by introducing an aqueous solution of labeled simple organic materials. The Gas Exchange Experiment also looked for metabolic processes, but by wetting Martian soils with a more complex and unlabeled nutrient solution.

While not principally a life detection instrument, the landers also carried a GCMS which could detect organic compounds in surface material, and measure the composition of the atmosphere. They also carried an x-ray fluorescence spectrometer to measure the abundance of selected elements in Martian surface material. In addition to determining the composition of surface materials, these data provided chemical and mineralogical information to help interpret the biology experiments.

The remaining lander experiments were not directly related to the biology investigation. The lander meteorology sensors recorded the pressure, temperature and wind velocity to help characterize Martian weather systems. The lander seismometers were designed to characterize the background noise level and to listen for major seismic events which would provide information on the interior structure of the planet. An array of magnets of differing strengths was attached to the sampling arm and to the top of the lander. By monitoring (with the camera) the accumulation of particles on these magnets, information on the abundance and composition of magnetic minerals could be obtained. Finally, the physical properties of the soil could be ascertained from

engineering data such as variations in motor currents from the sampler arm during digging operations (see also MARS: SURFACE).

The communication system (along with a tracking system) on the orbiters and landers was also used for science. The orbiter radios mapped the planet's gravity field, measured its surface relief and determined local atmospheric temperature profiles during occultation events. Lander radios were used to determine lander locations, the spin rate of the planet and the orientation of the spin axis.

Mission profile

Viking 1 and 2 were launched respectively on 20 August and 9 September 1975 and were inserted into elliptical orbits around Mars on 19 June and 7 August 1976. After several weeks of surface observations, a landing site was selected and the landing sequence was initiated. The lander separated from the orbiter and oriented itself for a 4 km s^{-1} entry into the Martian atmosphere at about 300 km above the surface. An ablatable aeroshell protected the lander from the heat of entry. At 6 km above the surface, a parachute was deployed, the aeroshell was jettisoned and the three lander legs were extended. At 1.5 km, retro-rockets were fired to slow the lander to several m s^{-1} and eliminate horizontal drift. VL-1 touched down on 20 July 1976 in Chryse Planitia (22°N, 48°W) at about 4 p.m. local time; VL-2 landed on 3 September 1976 in Utopia (44°N, 226°W) at about 10 a.m. local time. Both landings were successful.

After landing, there were several months of intense activity. The cameras systematically returned images

Table 1. Science investigations and instrumentation.

Investigation	Instrumentation
Orbiter investigations	
Orbiter imaging	Two vidicon cameras
Water vapor mapping	Near-infrared grating spectrometer
Thermal mapping	Solar and infrared radiometers
Entry science	Retarding potential analyzer, mass spectrometer, pressure, temperature and acceleration sensors
Lander investigations	
Lander imaging	Two facsimile cameras
Biology	Carbon Assimilation, Labeled Release, and Gas Exchange Experiments
Molecular analysis	Gas chromatograph–mass spectrometer (GCMS)
Inorganic analysis	X-ray fluorescence spectrometer
Meteorology	Pressure, temperature, wind velocity sensors
Seismology	Three-axis short-period seismometer
Magnetic properties	Permanent magnets on sampler arm
Physical properties	Various engineering sensors
Orbiter and lander investigations	
Radio science	Orbiter and lander communication systems

of the entire panorama around the lander. They also photographed the sky, the Sun, small permanent magnets, trenches dug by the sampler arm and rocks that were intentionally displaced. The meteorology boom was deployed and began returning weather data. Seismic experiments were initiated, although the seismometer at VL-1 failed to uncage (the VL-2 seismometer operated nominally). Numerous soil samples were acquired and subjected to chemical and biological analysis.

The primary mission was to last 90 days for each lander. However, the mission was repeatedly extended as long as the spacecraft remained healthy and returned useful data. The first hardware problem occurred in September of 1977 when VL-2 was no longer able to communicate directly with Earth, but it was not shut down until 12 April 1980. Leaking attitude control propellant left the VO-2 spacecraft unable to align itself with the Sun and it ceased operations on 25 July 1978. VO-1 was also running out of fuel and was commanded off on 7 August 1980. The mission finally ended on 13 November 1982 when contact was lost with VL-1.

Scientific results

Biology

The most significant result was the lack of detection of organic compounds at either landing site by the GCMS experiment. The GCMS was extremely sensitive to organic compounds and could detect them at the parts per billion level for large molecules, a level some 100 times less than those found in deserts on Earth. Yet the results were unambiguously negative. The absence of organic matter, regardless of the results of the biology experiments, argued strongly against the possibility for life in Martian soil.

While the three biology experiments produced results which in some ways simulated life, in detail they were more consistent with the presence of soil oxidants. The Gas Exchange Experiment showed a significant increase in CO_2 and O_2 after the soil was humidified. The CO_2 can be explained by the displacement of adsorbed CO_2 molecules by water vapor, but the O_2 requires some other explanation. The observed 200-fold increase in O_2 is best explained by the decomposition of peroxides in the Martian soil. Such peroxides are theoretically expected from photochemical processes in the Martian atmosphere. Also, a highly reactive oxidant in the Martian soil could readily explain the absence of organic material.

The Labeled Release Experiment showed a surge in radioactive CO_2 after wetting the soil with its mixture of nutrients. Taken by itself, this result satisfied the criteria for a biological interpretation. However, when viewed in context with the other biology experiments and the GCMS, this too was believed to be a chemical rather than biological result. Peroxides present in the soil would have oxidized one of the compounds in the nutrient solution (formic acid) and produced CO_2 gas. Also, if microorganisms were involved, a second injection of the nutrient solution should have produced a further increase in CO_2 levels, yet none was observed.

The results of the Carbon Assimilation Experiments were more complicated, but they too favor a chemical explanation. The amount of fixed carbon produced in these experiments was generally higher than the expected background levels, particularly the first experiment at VL-1. This experiment also showed a temperature sensitivity to the amount of fixed carbon produced. It is now believed that an iron-catalyzed reaction was the source of the signals seen in the Carbon Assimilation Experiment.

Meteorology

Lander meteorological measurements showed that the average surface pressure on Mars is about 7 mbar. However, it varies semiannually owing to the condensation and sublimation of CO_2 in the polar regions. The amplitude of the

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

fluctuation is about 2.3 mbar, or about one-third of the annual mean. Thus, the seasonal polar caps on Mars are made of dry ice (frozen carbon dioxide).

The pressure data also revealed eastward-traveling weather systems and westward-propagating thermal tides. The temperature at the Viking sites ranged from 180 K to 240 K depending on time of day and season and was more repeatable during summer than winter. Winds were found to be strongest during winter with gusts up to 30 m s^{-1}. During summer winds were calm by comparison.

During autumn of the first year, the sky opacity at the Viking sites increased dramatically on two occasions. These increases were associated with the development of global scale dust storms. No such storms were observed during the second and third (Mars) years of operations.

Seismology

No major seismic events were detected. A magnitude 2.8 event (on the Richter scale) was detected 110 km from the Viking Lander 2 site. The signal was significantly damped within minutes, indicating the likely presence of water and gas within the crust. From shear wave reflections, the crust was estimated to be about 15 km thick in this region. The natural background level of seismic activity was found to be very low. Winds were a major source of the seismic background because of the poor coupling of the seismometer to the ground.

Atmospheric composition

The composition of the Martian atmosphere was measured by the Viking landers during entry and descent and while on the surface. The principal components are CO_2 (95.32%), N_2 (2.7%), Ar (1.6%) and O_2 (0.13%). The mean molecular weight is 43.34. These gases were found to be well mixed up to 120 km altitude. Above 120 km they begin to diffusively separate. In the ionosphere O^+ was found to be the dominant species with CO^+ about an order of magnitude less abundant.

Isotopic ratios of various elements were also measured. The stable ISOTOPES of carbon and oxygen were found to be similar to Earth's, but $^{15}N/^{14}N$ was enriched by 60%. The enrichment is due to the selective escape of the lighter isotope with respect to the heavier one, and it implies that Mars may have had a denser atmosphere in its distant past. $^{40}Ar/^{36}Ar$ and $^{129}Xe/^{132}Xe$ were also found to be enriched with respect to terrestrial values. In this case, however, the enrichment is thought to be due to removal of a substantial fraction of Mars' early atmosphere by impacts events followed by the accumulation of the radiogenic isotopes ^{40}Ar and ^{129}Xe.

Atmospheric water detection

Water vapor in the Martian atmosphere was found to vary seasonally and spatially. On average, a column of Martian air contains the equivalent of a layer of liquid water about 10 μm deep. EARTH'S ATMOSPHERE, by comparison, contains 2–4 cm of water. Approximately 100 μm of water vapor was observed over the north polar cap during summer. Very little water vapor was observed over the south polar cap during its summer. This difference in behavior is due to the different compositions of the summer residual caps: the north summer cap is made of water ice, while that in the south is made of CO_2 ice.

Atmospheric structure

During their descent to the surface, the Viking landers recorded the spacecraft deceleration history. These data were used to construct a temperature profile from near the surface to about 200 km. The profiles at the two landing sites were found to be very similar even though they were collected at different locations and times. Temperatures decreased from 230 K near the surface to about 150 K aloft, and they showed considerable structure possibly due to thermal tides and/or gravity waves.

Thermal mapping

Surface temperatures were mapped by the IRTM instrument. Highest temperatures (300 K) occur in early afternoon in southern subtropical latitudes during summer. Lowest temperatures (130 K) occur in polar regions during winter. The daily variation in surface temperature was used to map the thermal inertia of the soil. Thermal inertias range from about 50 to 500 SI units and indicate fine sandy material and well-consolidated bedrock, respectively. Atmospheric temperatures near 25 km were also mapped and showed great sensitivity to dust.

Orbiter imaging

Over 50 000 images were returned by the Viking orbiters. The images covered the entire planet at a resolution of 200 m and large areas at resolutions as high as 7.5 m. Much of the planet has been photographed in color and stereo, although at lower resolution. Orbiter cameras also imaged the moons of Mars (PHOBOS AND DEIMOS), and photographed the shadow of Phobos as it crossed the VL-1 site.

For almost two Mars years, the orbiter cameras monitored weather patterns, the advance and retreat of the polar caps, dust storm activity and the continual redistribution of fine-grained material on the surface. They returned pictures of enormous volcanoes, a vast equatorial canyon system, numerous impact craters, polar layered deposits and fluvial features suggesting catastrophic flooding and possible climate change.

The northern hemisphere was found to be geologically young and covered with volcanic fields. The giant shield volcanoes in the Tharsis region have relatively few craters indicating that volcanism lasted for an extended period of time. In contrast, the southern hemisphere is old and heavily cratered. Parts of its surface may have formed at the end of the heavy bombardment period 3.8 billion years ago.

Soil properties
The fine-grained material at the two Viking sites has similar elemental abundances. Silicon is the most abundant element (21%), followed by Fe (13%), Mg (5%), Ca (4%), Al (3%) and S (3%). The surprisingly uniform soil composition suggests planetary-scale homogenization of the soil by winds. The soil is weakly cohesive and has a bulk density of about 1.2 g cm^{-3}. Magnets on top of the landers attracted soil-derived airborne dust. About 2% of the soil contains magnetic material with maghemite (γ-Fe_2O_3) being the most likely candidate. A plausible model for the soil material is that it is a basaltic weathering product.

Vilnius University Observatory

Vilnius University Observatory, the astronomical observatory of Vilnius University, Lithuania, was founded in 1753. In 1831, when Vilnius University was closed, the observatory was entrusted to the Academy of Sciences of St Petersburg (Russia) and continued its activities until 1881. The Observatory resumed its operation in 1919 when Vilnius University was reopened. Activities of the observatory were again interrupted by Nazi occupation (1941–44) and resumed after World War II. Its main instruments are a 60 cm reflector located at Moletai Observatory 80 km north of Vilnius and a 48 cm reflector located at the Maidanak observing site in Uzbekistan, Central Asia. Present staff consists of eleven astronomers and six technicians. Activities are in the field of construction of photometric equipment, investigation of physical properties of stars, interstellar matter and galactic structure.

Virgo

(the Virgin; abbrev. Vir, gen. Virginis; area 1294 sq. deg.) an equatorial zodiacal constellation which lies between Leo and Libra, and culminates at midnight in mid-April. Its origin dates back to Babylonian times and it has been associated with numerous female deities, including Ishtar (Babylonia), Isis (ancient Egypt), Demeter (ancient Greece) and Astraea (ancient Rome). Its brightest stars were catalogued by Ptolemy (*c*. AD 100–175) in the *Almagest*.

Virgo is the second-largest of the 88 constellations but is not particularly prominent, save for its brightest star, α Virginis (Spica or Azimech), magnitude 1.0. Other bright stars include γ Virginis (Porrima), a fine binary with pale yellow (F0) components, both magnitude 3.6 (combined magnitude 2.7), separation 2.7″, period 168.7 years (closest 2005), ε Virginis (Vindemiatrix or Almuredin), magnitude 2.9, ζ Virginis, magnitude 3.4, and δ Virginis, also magnitude 3.4. There are five other stars of magnitude 4.0 or brighter.

There are no bright open star clusters or nebulae in Virgo, but the constellation contains a large number of galaxies, many of which are members of the Virgo Cluster, which extends into neighboring Coma Berenices. The brightest members of the Virgo Cluster are the giant elliptical galaxies M49 (NGC 4472), 8th magnitude, and M87 (NGC 4486, Virgo A), 9th magnitude, which is a strong x-ray and radio source and from which emanates a jet of material thought to have been expelled from a black hole at its center. An interesting non-cluster galaxy is M104 (NGC 4594, the Sombrero Galaxy), an 8th-magnitude spiral with a dark lane of obscuring dust presented almost edge-on.

The constellation also contains the first quasar to have been detected (in 1963), 3C 273, magnitude 12.9.

Virgo A

The brightest radio source in the constellation of Virgo. Virgo A, otherwise known by the catalog number 3C 274, coincides with M87 a giant elliptical galaxy, and active galaxy, located at a distance of some 50 million light-years in the Virgo cluster of galaxies. Although part of the radio emission comes from two elongated lobes, one on either side of the center of the galaxy, the lobes, which span an overall diameter of about 16 000 light-years, are contained within the optical galaxy (rather than, as with most radio galaxies, extending beyond its visible perimeter). The majority of the radio output comes from a jet that emerges from the core of the galaxy and stretches out some 8000 light-years into one of the two lobes.

The jet radiates at all wavelengths from x-ray to radio. Like the lobes, it emits synchrotron radiation (radiation that is generated by electrons moving at very high speeds in magnetic fields). The motion of bright knots in the jet indicate that they are traveling outwards at about half the speed of light and implies that the electrons themselves must be traveling within the jet at speeds at least as high, if not higher, than this.

With a mass of at least 10^{12} solar masses, M87 is an exceptionally massive galaxy. Observations of the rates at which stars and gas clouds revolve within its central core, and of the way that stars appear to be concentrated at its center, imply that M87 contains a compact massive object, most probably a black hole, of about 3 billion solar masses.

Virgo Cluster

The Virgo cluster is the nearest and best-studied rich CLUSTER OF GALAXIES, lying at a distance of about 55 million light-years in the constellation of VIRGO. Figure 1 is a map of the distribution of nearby galaxies (as determined by their REDSHIFTS) in a 1500 square degree region of the constellation of Virgo. The Virgo cluster is the strong, somewhat irregular, concentration of galaxies at the center. In three-dimensional (3D) space, the Virgo cluster constitutes the nucleus of the Local Supercluster (LSC) of galaxies, in whose outskirts our MILKY WAY GALAXY is situated.

As early as 1784, CHARLES MESSIER noted an unusual group of 'nebulae' in Virgo. Fifteen out of the 109 famous 'Messier objects' are, in fact, member galaxies of the Virgo cluster. However, only in the 1920s, following EDWIN HUBBLE's proof of the extragalactic nature of those 'nebulae', was Messier's group understood as a self-gravitating system of hundreds of galaxies, and the first systematic investigations of the Virgo cluster, as it was henceforth called, were carried out by HARLOW SHAPLEY and others.

Virgo was the first galaxy cluster to be studied dynamically by Smith and Zwicky in the 1930s. Their work showed that the dynamical mass of Virgo, estimated by using the virial theorem

$$2T + U = 0$$

where T and U are the time-averaged kinetic energy and potential energy of the relaxed system, was much larger than the mass inferred by integrating the light of all the galaxies in the cluster and multiplying by a mass-to-light ratio (M/L) like the average of stars in the solar neighborhood. This was the first clear detection of 'DARK MATTER,' or more properly, non-luminous mass. The distribution of galaxies in the direction of Virgo in redshift space is shown in figure 2, and figure 3 displays the histogram of galaxy velocities inside a circle of 6° radius centered on the core of the cluster at 12^h28^m and $+10^\circ28'$.

The Virgo cluster lies at the center of the LSC, first dynamically studied by G de Vaucouleurs and collaborators in the 1950s. The Milky Way appears to be falling into the Virgo cluster, relative to the general expansion of the universe, with a velocity of $\sim$250 km s^{-1}. That is to say, we are still moving away from the cluster core with an apparent velocity, cz, of $\sim$1100 km s^{-1}, but that velocity is 250 km s^{-1} less than it would have been if the cluster had no mass. Curiously, the M/L for the whole LSC derived from this Virgo infall is similar to that derived via the virial theorem for the dynamically relaxed cluster core; both M/L values, when applied to the mean luminosity density of the universe derived from redshift surveys, imply a mean matter density of the universe that is only 1/4 to 1/3 of the critical density.

The kinematics of the cluster is quite complex as can be seen in figures 1 and 4. There are two main concentrations of galaxies; the largest and densest is centered on the well-known galaxy M87 (NGC4486) which is both a strong radio source (VIRGO A) and a strong x-ray source. This subcluster, at $12^h30^m.8 + 12^\circ23'$, is also a strong x-ray source produced by a reservoir of extremely hot intracluster gas. This INTRACLUSTER MEDIUM is at a temperature of $\sim10^7$ K, emits thermal bremsstrahlung radiation and is a major contributor to the total mass of the system. The southern large subcluster is centered on M49 (NGC 4472) at $12^h29^m.8 + 8^\circ00'$, the most luminous galaxy in the cluster, but is significantly less massive than the M87 subcluster. The total mass of the Virgo core region is $\sim10^{15}M_\odot$, that of the M87 subclump $\sim3 \times 10^{14}M_\odot$ and the M49 subclump is $\sim1 \times 10^{14}M_\odot$, assuming a distance to the cluster core of 16 Mpc. The cluster distance of $\sim$16 Mpc has been estimated via a variety of techniques including measurements of Cepheids to six galaxies with the Hubble Space Telescope, studies of globular clusters and planetary nebulae (PNe) luminosity functions, and surface brightness fluctuations (SBFs).

At present, approximately 1300 member galaxies of the Virgo cluster are known, most of which are very faint DWARF GALAXIES (but this number is bound to grow fast in the near future, as ever fainter members are going to be detected with improving techniques). Their projected positions within the cluster—spread over a large sky area of roughly 100 square degrees, or 500 full moons (see figure 4)—reveal a rich substructure. The Virgo cluster indeed represents the most common type of clusters of galaxies that are loosely concentrated and 'irregular'. Several gravitationally bound subsystems of galaxies have been identified. Of these, the subcluster centered on Messier 87 is by far the largest and most massive structure (the Virgo cluster proper, so to speak)—and M87 itself, the giant, active galaxy with its famous jet, can truly be regarded as the heart of the Virgo cluster. The smaller subclusters seem to be in a state of merging with the M87 subcluster. In this sense, the Virgo cluster (like many, if not most, clusters of galaxies) is still in the making.

The Virgo cluster has always been, and still is, one of the most important stepping stones for the cosmological distance scale. Much of the current debate on the value of the HUBBLE CONSTANT boils down to a debate on the mean distance of the Virgo cluster (see below).

A new and very exciting era of Virgo cluster research has recently been opened by the first detection of intracluster PLANETARY NEBULAE (PNe) and single RED GIANT STARS, i.e. stellar objects that are not bound to a single galaxy but to the cluster as a whole. This adds a whole new population to the cluster, which in the future will be used to explore the 3D structure and dynamical history of the Virgo cluster.

Global structure

The primary optical database for the galaxy content of the Virgo cluster is the Las Campanas photographic survey, carried out in the 1980s by Allan Sandage and collaborators, and encapsulated in the Virgo Cluster Catalog (VCC). Figure 4 is a map of the ca 1300 galaxies in

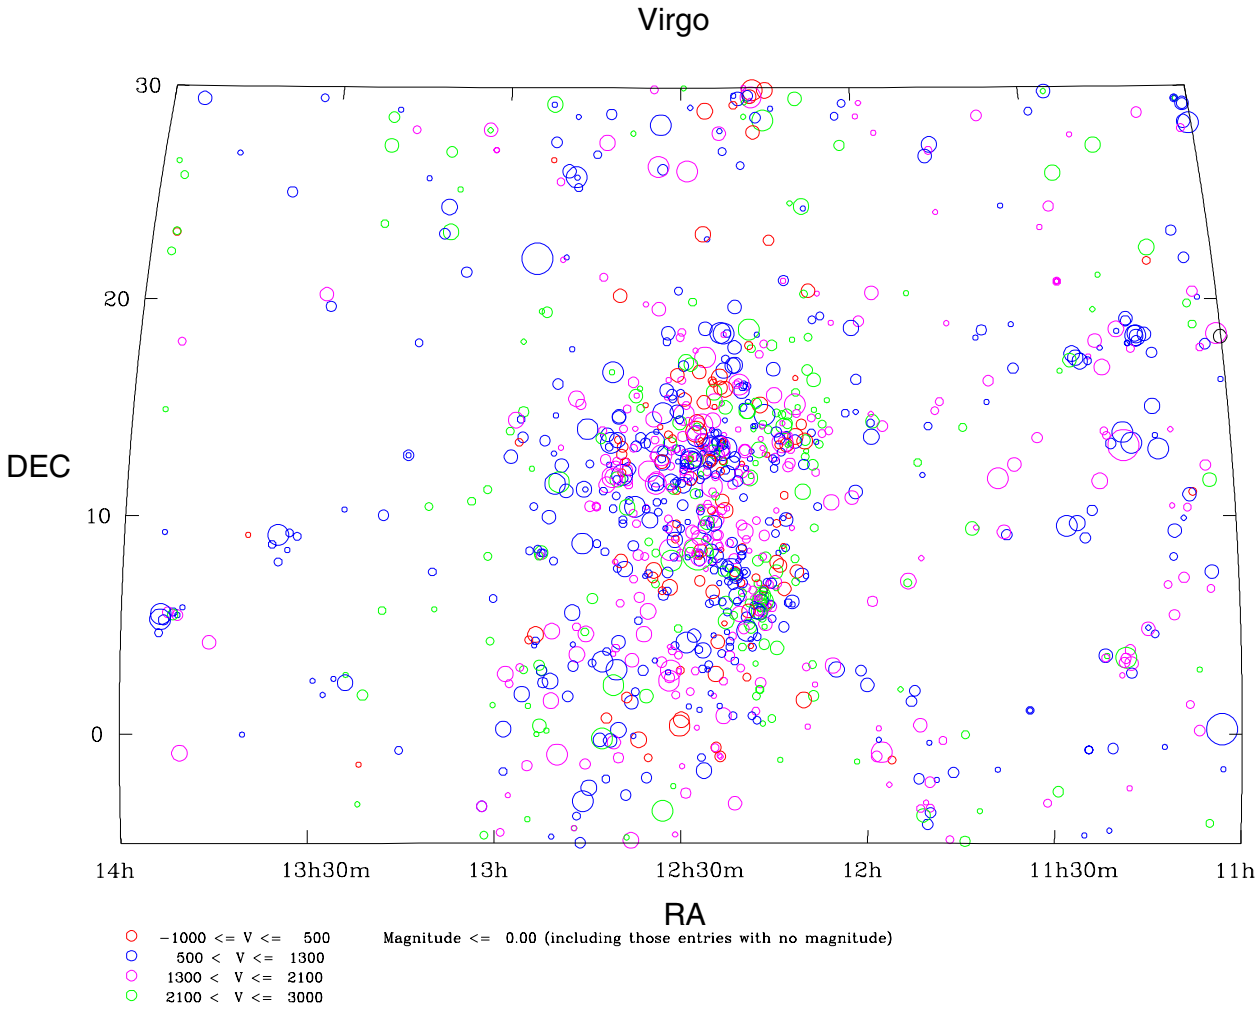

Figure 1. The distribution of nearby galaxies (apparent recession velocities less than 3000 km s^{-1}) in the direction of Virgo. Each circle represents a galaxy; the size of the circle represents its apparent brightness. Galaxies with apparent velocities less than 500 km s^{-1} are shown in red, those above 2100 km s^{-1} in green, and those between 500 and 1300 km s^{-1} and between 1300 and 2100 km s^{-1} in blue and magenta, respectively. **This figure is reproduced as Color Plate 63.**

the sky area covered by the Las Campanas survey that were judged to be members of the Virgo cluster. The membership criteria were based on (1) the morphological appearance of the galaxies, e.g. dwarf ellipticals have a characteristically low surface brightness, and/or (2) the measured radial velocities, which for members have to be smaller than ca 2700 km s^{-1} (heliocentric). Velocities are at present available only for the brightest 400 members (but this number, too, will steadily grow in the future).

The magnitude limit of completeness of the Las Campanas survey is around apparent blue magnitude $B = 18$ or, if we assume a mean distance of 16 Mpc, absolute magnitude $M_B = -13.0$. However, fainter members (up to $B = 20$) were included as well. For comparison, the brightest cluster members, M49 and M87, have $B \simeq 9.0$ and $B \simeq 9.5$, respectively. Thus the known cluster population spans a range of ≈10 000 in luminosity.

From the distribution of symbol sizes in figure 4 one can obtain a feeling of the exponentially growing luminosity function of galaxies. Of the 1300 known members, 850 alone are of the dwarf elliptical (dE) type. The basic characteristic of dEs is a relation between luminosity and surface brightness: fainter dwarfs have also lower surface brightness. As the detection limit for extended objects such as galaxies is set by the surface brightness rather than total magnitude, it is clear that many hundreds, if not thousands more, of extremely faint and diffuse dE members of the Virgo cluster have yet to be discovered by future deep surveys. These will be the analogs of the dwarf spheroidal companions of our Galaxy, which are as faint as $M_B = -8$ (corresponding to $B \approx 23$ at Virgo distance).

Among the remaining 450 member galaxies, there are roughly 80 elliptical (E) and S0 galaxies, 130 spirals, 90 irregulars and 90 dwarf galaxies of intermediate type

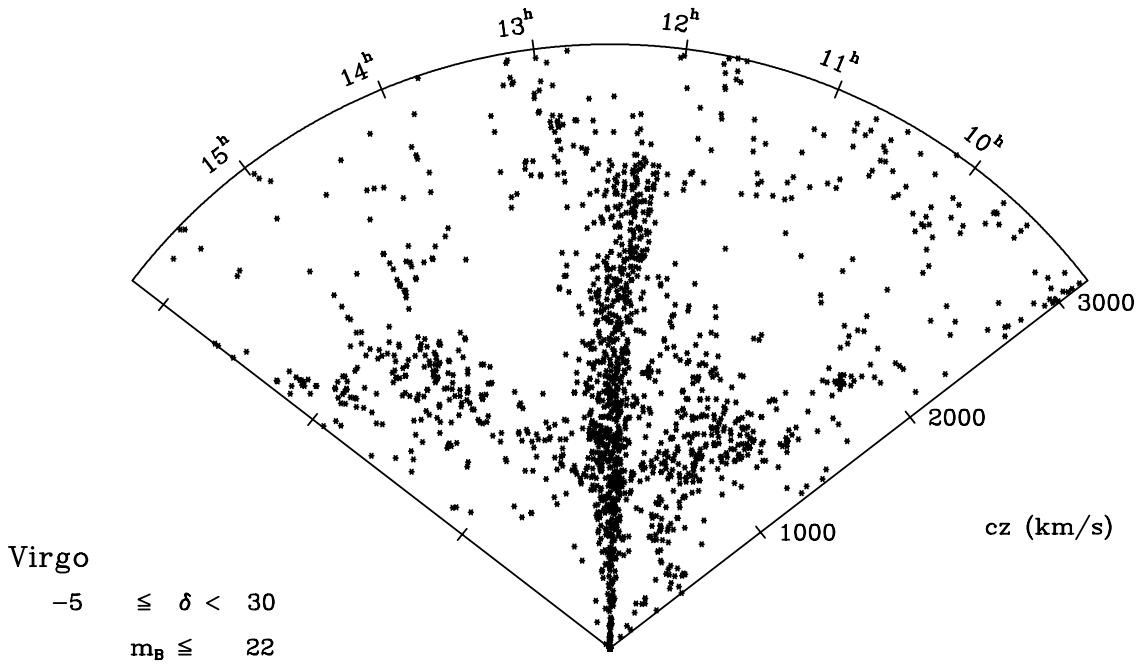

Figure 2. The distribution of galaxies in redshift space in the direction of the Virgo cluster. We are at the apex of the wedge. The main body of the cluster is the picturesquely named 'Finger of God' at the center of the wedge. This is not a real feature. Its extension along the line of sight in this plot is a measure of the internal velocity dispersion (and thus the mass) of the galaxy cluster so that a galaxy with a given radial velocity is placed in front of or behind its true position. The large and diffuse structure seen to the right (10.5^h–11^h and 1100 km s^{-1}) of Virgo is the Leo group.

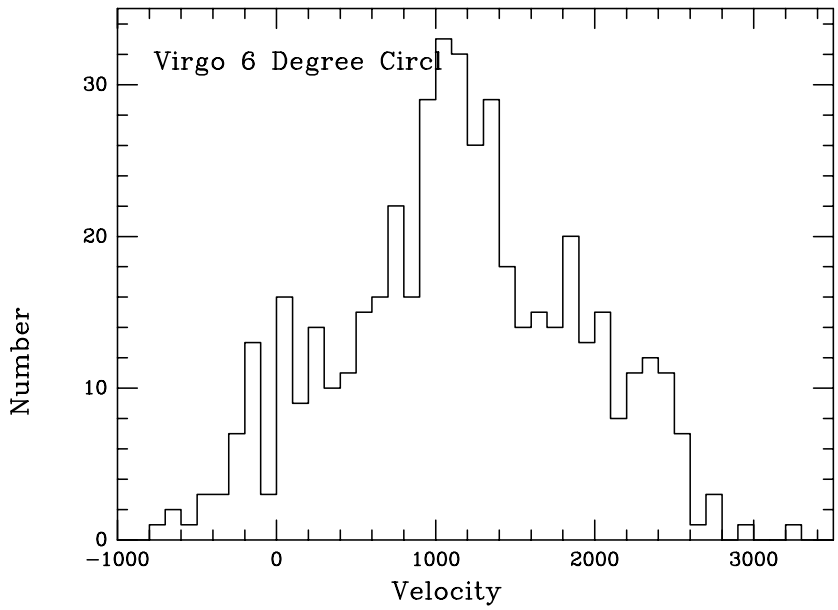

Figure 3. Histogram of apparent velocities for galaxies within a 6° radius of the center of the Virgo cluster. The breadth of the distribution from 0 to 300 km s^{-1} accounts for the 'Finger of God' structure in figure 2.

(Irr–dE). The distribution of these morphological types within the cluster varies considerably—in accord with Dressler's GALAXY 'MORPHOLOGY–DENSITY RELATION': Es and S0s are strongly confined to the regions of highest galaxy density, defining the 'skeleton' of the cluster (dwarf Es only to a slightly lesser degree), while spirals and irregulars

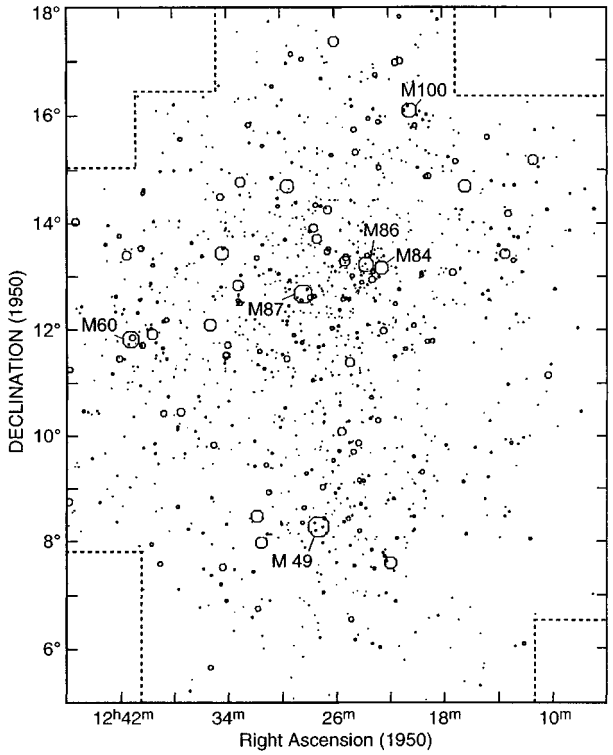

Figure 4. Map of the Virgo cluster as it appears in the sky. All cluster members are plotted with luminosity-weighted symbols. The symbol size (area) is proportional to the luminosity of the galaxy. The most prominent Messier galaxies are indicated. The broken lines indicate the boundary of the Las Campanas survey.

(S+Irr) are very weakly clustered, lying preferentially in the cluster outskirts.

This morphological segregation is also reflected in the velocity distributions. An analysis of the radial velocity data so far available gives a velocity dispersion (1σ) of $\approx$600 km s^{-1} for early-type galaxies (E, S0, dE), but one of $\approx$750 km s^{-1} for late types (S+Irr), i.e. late types are more dispersed in space and velocity. Moreover, the velocity distribution for S + Irr is distinctly non-Gaussian with a low-velocity and a high-velocity wing. These wings are probably caused by infalling and expanding shells of galaxies around the cluster core. Most Virgo spirals and Irrs may have fallen only recently, or are still in the stage of falling, into the cluster from the surroundings, explaining their lack of dynamical relaxation (virialization). Those spirals observed to be H I deficient have apparently already fallen through the cluster core.

The all-cluster mean heliocentric velocity is $\langle v\rangle_{\rm helio} \simeq$ 1050 km s^{-1} (there is no difference with respect to type). Note that this is not the cosmic (Hubble flow) recession velocity of the Virgo cluster, $\langle v\rangle_{\rm c}$, which can be derived by (1) correcting for the solar motion with respect to the centroid of the Local Group by subtracting $\approx$100 km s^{-1} and (2) correcting for the Virgocentric infall (deceleration) of the Local Group by adding $\approx$250 km s^{-1}. This finally gives $\langle v\rangle_{\rm c} \simeq 1200$ km s^{-1}.

Subcluster dynamics

The primary structural characteristic of the Virgo cluster (cf figure 4) is certainly its high degree of irregularity and subclustering. Several subclumps (gravitationally bound subclusters) of galaxies suggest themselves: a main northern subclump around M87, M86 and M84, a southern clump around M49 and possible subgroups around M60 and M100. The global structure of Virgo seems defined by two main axes: one N–S, i.e. M100–M86/M87–M49, and one E–NW, i.e. M60–M87–M86/M84. Remarkably, the former axis is nearly perfectly aligned with the position angle of the outer isophotes of M87, while the latter is perfectly aligned with the jet axis of M87. This shows once more that M87 is the heart of the Virgo cluster.

The reality of the main N–S double structure cannot be doubted, because the northern and southern subclumps are sufficiently well separated. Both have a very similar mean radial velocity, which would suggest that they are at the same distance, i.e. lying in the plane of the sky (however, see below). The southern M49 clump is rather spiral rich and has a surprisingly small velocity dispersion of $\sigma_v \approx 500$ km s^{-1}.

The core region with M87, M86 and M84 is much harder to disentangle. The key observation here is that the velocity distribution of galaxies in this northern clump (especially for dEs) is strongly skewed towards low velocities. In the low-velocity tail we find the most blueshifted galaxies known in the sky (the record holder, VCC846, has $v = -730$ km s^{-1}). These objects tend to be clustered around M86, which itself has a negative velocity ($v = -227$ km s^{-1}). On the other hand, the velocity distribution is peaked around $v = 1300$ km s^{-1}—nearly coinciding with the velocity of M87 ($v = 1258$ km s^{-1}).

A clear asymmetry in the velocity distribution of a cluster of galaxies is almost certainly an indication of ongoing subcluster merging. In the Virgo cluster we seem to witness the merging between a subclump around M87 and another clump around M86 (or rather, the infall of the M86 subcluster into the more massive M87 subcluster, see below). Both giant galaxies must be the centers of huge swarms of dwarf galaxies. M86 is apparently falling into, or through, the M87 subclump from the back, hence with a high relative (negative) velocity, dragging along its dwarf companions. (The giant galaxy M84, very close to M86 in the sky, but with $v = 1000$ km s^{-1}, has to be a member of the M87 subcluster.)

This whole picture is fully confirmed by an analysis of the x-ray structure of the Virgo cluster. Figure 5 shows, as a gray-scale image, the distribution of the x-ray intensity in the Virgo cluster as measured by the ROSAT x-ray satellite. The x-rays originate from the hot intracluster gas via thermal bremsstrahlung. The gas feels the same gravitational potential of the cluster as the galaxies. The global appearances of the cluster in the x-rays and in the optical (figure 5 versus figure 4) are therefore very similar. However, the main subclusters around M87, M86 and M49

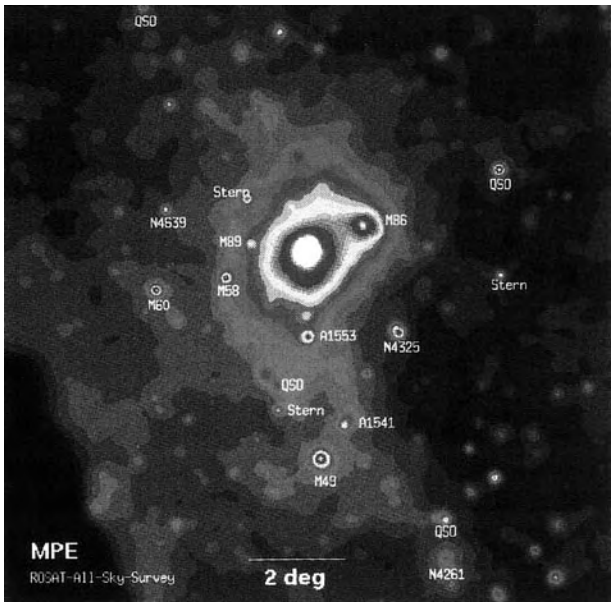

Figure 5. X-ray image of the Virgo cluster from the ROSAT All-Sky Survey. Various foreground stars, quasars, Abell clusters and Virgo cluster members (NGCs and Messiers) are indicated. The large, bright spot is centered on M87. Compare with figure 4. Courtesy of Dr H Böhringer and the MPE Garching.

are popping out much more clearly in the x-ray image. M87 has a huge x-ray halo and is obviously the center of the dominating subcluster in Virgo. M86 has a large gas halo as well—larger than expected for an isolated giant, but of the right order for a whole subcluster. The infall of this subcluster from the back is supported by the observation of a ram pressure plume in the x-ray structure of M86.

Subcluster merging has turned out to be a general feature of cluster of galaxies, even with so-called 'regular' ones, such as the COMA CLUSTER. This is not unexpected in a bottom-up (clustering) picture of structure formation, as described by the much favored 'cold dark matter' scenario.

Under the (tested) assumption of hydrostatic equilibrium, the x-ray halo profiles can be used to calculate the gravitational masses of the subclusters that are binding the gas. For the dominating M87 subcluster the integrated mass out to 1 Mpc from M87 amounts to $M \simeq 1.4 \times 10^{14} M_{\odot}$, of which 14% is in the gas, and only 4% in the galaxies. This means that the cluster is essentially dark matter, second comes the intracluster gas and only in third place the luminous matter in galaxies, with a correspondingly high mass-to-light ratio of $M/L \approx 500$. This is quite typical for clusters of galaxies.

Distance and depth

The mean distance of the Virgo cluster is still a matter of debate. Distances quoted range from 14 to 22 Mpc. In general, the most reliable extragalactic distance indicators are the Cepheids. Cepheids at (and slightly beyond) the Virgo cluster distance are now within the reach of the HUBBLE SPACE TELESCOPE (HST). This achievement was so long awaited that the first Cepheid-based distance determination of a Virgo cluster spiral in 1994 (M100 at 17 Mpc) had an enormous impact. The caveat with this was, and is, that spirals tend to avoid the cluster core and may be in the field far off the cluster (cf also above). It has been conjectured that M100, as well as other spirals located by Cepheids with HST later on, might lie at the near side of the cluster.

On the other hand, from work based on the TULLY–FISHER (TF) RELATION, which allows the distance to an individual spiral galaxy to be given with an accuracy of $\approx$0.4 mag, there is consistent evidence that Virgo late types are distributed in a prolate cloud, or filament, stretching—nearly along our line of sight—from the cluster backwards to the so-called 'W cloud' at twice Virgo's distance. Probably this is part of a very long filament that is running way back to the 'Great Wall' at the distance of the Coma cluster. On the near side of Virgo it might even be connected with the 'Coma–Sculptor cloud' that is running through us, i.e. includes the Local Group.

There is a hint, again from TF distances, that the southern M49 subcluster is lying significantly in the back of the M87 subcluster. If so, the M49 subcluster must be infalling from the back with a velocity of several 100 km s^{-1}, as the mean observed velocities of the two subclusters are very similar. The merging of subclusters along the large-scale filament in which they are embedded is plausible.

To determine the distance of the core of the Virgo cluster one should avoid late-type galaxies. The safest would be to use only elliptical and dwarf elliptical members. Unfortunately, the primary distance indicators here, RR LYRAE STARS, are much too faint at the distance of Virgo even for HST. The secondary distance indicators which can be applied to Virgo ellipticals give controversial results: globular clusters, D_n–σ and novae tend to give large distances ($D \approx 20$ Mpc), SBFs and PNe lead to a small $D \approx 16$ Mpc. Great efforts are spent in the application of the SBF method because its claimed distance uncertainty for an individual galaxy is almost as small as with Cepheids ($\leq$0.2 mag) and hence would allow us to resolve the cluster depth (the front-to-back depth is about 2 Mpc, or 0.2 mag, if the cluster is spherical). Individual Virgo E distances, with a surprisingly large scatter, have indeed been reported, but there is still some concern whether all variations of the stellar content of ellipticals, on which the method critically depends, are sufficiently well understood. For instance, the SBF distance of M49 is much smaller than the (probably more reliable) TF distance of the whole M49 subcluster, which means that either M49 is lying in the foreground, being projected on top of the background 'M49' subcluster by chance, or the SBF method is wrong.

Some hope for the future is resting with dwarf ellipticals, of which there is an almost inexhaustible reservoir in the cluster. A first, very promising

application of the tip-of-the-red-giant-branch (TRGB) distance indicator to a particular dE based on HST observations has given $D \simeq 16$ Mpc. A recent claim that dEs are distributed in a prolate structure pointing towards us, based on the shape of the luminosity profile of these galaxies, will soon be tested by an extension of the SBF method to dEs.

A new tool to determine the mean distance and depth of the Virgo cluster core may be provided by the recently discovered population of free-floating giant stars and PNe. Such a population has long been suspected in clusters of galaxies, as stars will be ripped from galaxies by tidal encounters in the cluster core, a process called 'galaxy harassment'. The data available so far suggest that approximately 10% of the stellar mass of the Virgo cluster is in intergalactic stars. There are ongoing programs with large telescopes to measure the radial velocities and metallicities of a large number of intracluster PNe. These data will provide crucial constraints on the dynamical state and history of the Virgo cluster.

Virgo Gravitational-wave Interferometer (VIRGO)

VIRGO is a collaboration between Italian and French research teams to construct an interferometric gravitational wave detector at Cascina, near Pisa, Italy. It relies on a technique called laser interferometry to measure with immense accuracy the minute changes in distance induced by gravitational waves from astronomical sources.

The VIRGO project plans to set up a laser interferometer made of two, 3 km long, orthogonal arms. Light from a laser is split into two beams which travel down the arms and are then reflected back by mirrors. In effect, multiple reflections will increase the optical length of each arm to 120 km. Variations in the pattern of interference between the returning beams will enable gravitational waves to be detected and their sources to be identified.

VIRGO will be sensitive to gravitational waves at frequencies from 10 to 6000 Hz. It should be able to detect radiation produced by supernovae and by the coalescence of binary systems in the Milky Way and other galaxies, for instance from the Virgo cluster.

It will use high-power ultrastable lasers and high-reflectivity mirrors, as well as seismic isolation and control of position and alignment. Each optical component is isolated by a 10 m high elaborate system of compound pendulums, called a 'superattenuator'. The 6 km long, 1.2 m diameter evacuated tube through which the light beam passes will be one of the largest vacuum vessels in the world. The signals will be detected, registered and elaborated by computer.

Visual Binary Stars

Already since the early development of telescopes, an increasing number of stars—single to the naked eye—were found to consist of two or more components. They became known as 'double stars' (étoiles doubles, dvoinye zvozdy, Doppelsterne) and soon were too numerous to be explained as random pairings of stars in the sky. With increasing observing-time span, some pairs showed around 1800 that the components orbited one another. The English term 'BINARY STARS' tends to emphasize this gravitational connection. In distinction from close doubles recognized by stellar eclipses or by periodic changes of spectral-line shifts (photometric and spectroscopic binaries), the directly resolved objects are termed 'visual' although eyepiece observations are no longer the only method of study. Telescopes and techniques of the 20th century have improved the angular resolution to below 0.1 arcsec, but in order that components be separated, that is be recognised by their different positions in the sky, visual pairs are subject to at least one of two limitations.

(a) They are not very distant from Earth. Visual objects thus are predominantly of the more populous types in the solar neighborhood: stars from the middle and lower main sequence;
(b) The true distance between the components is not too small. The orbit periods are therefore generally much longer than in ECLIPSING and SPECTROSCOPIC BINARY STARS, and so it is important that measurements dating back 100 yr and more are available for many of them.

In addition, detection is impeded when the stars have a large brightness difference. Hence not many lowest-luminosity dwarf components, or companions of bright supergiants, are known.

Designations of visual double stars

The celestial position for J2000 (the beginning of the Julian year 2000) is generally used, for instance 07346 + 3153 means right ascension 7h 34.6m and declination 31° 53′ N (Castor). Cataloguing confusion can occur when the positions of faint stars are not well enough determined or when the transfer to J2000 ignored proper motions.

Also used are discoverers' codes, e.g. Bu 1077 for α Ursae Majoris (Dubhe) after the finding by S W BURNHAM. These letter codes are unambiguous but owing to their variety a bit cumbrous. The master file of visual double stars, maintained at the US Naval Observatory, Washington DC, and currently being revised, lists both these identifiers for nearly 100 000 entries, and in addition the Durchmusterung number (Bonn, Cordoba, Cape), if any.

The double-star catalogue by R G AITKEN contains objects discovered before 1927 in the sky north of −30° declination. Since it includes many well-known binaries, the ADS number is still used. Some publications cite the HIP number after the star catalogue from the HIPPARCOS satellite mission.

Some results of statistics

Adding all kinds of binaries, and with a statistical estimate of the occurrence of undetected, low-mass components, the fraction of stars on the upper and middle main sequence which are members of binary and multiple systems comes to about 80%. This membership rate decreases toward RED DWARF STARS, and for faint dM types—of which only the nearest are well studied—may be as low as 40%. Thus the most abundantly occurring stellar masses, around 0.2 of the solar mass, are less frequently found in binaries.

Very wide pairs have only a weak gravitational bond, which may be disrupted by fairly close random encounters with passing stars. As estimated from the star density in the Galactic disk, the limit of separations, below which a pair is expected to remain bound through its lifetime is at 10 000–20 000 AU (astronomical units), or 0.05–0.1 pc. Existence of orbit periods up to some millions of years is thus to be expected.

Inevitably some pairs of stars appear close together by chance alignment, although the components are at different distances and unrelated. These are 'optical' or 'perspectivic' double stars. Statistics show that the probability of a random alignment to within 5″ or so is quite low for stars down to about 12th magnitude. Most of the catalogued double stars thus are genuinely physical systems.

Observing techniques

Visual measurement by micrometer

The FILAR MICROMETER contains a set of thin wires, one movable against another with a precision screw, and mounted on a rotatable frame in the focus of a high-power eyepiece. This simple device supplies the position of one double-star component relative to the other in polar coordinates: the position angle (direction in the sky) counted from N over E, S, W from 0° to 360° by orientation of the frame, and the separation between stars in arcsec by the spacing of the wires. Since the eye has a good time resolution of 0.05 s, it can suppress much of the atmospheric turbulence, often reaches the diffraction-limited resolving power provided by the telescope aperture and may even recognise elongated double-star images below resolution. (The often-heard statement that atmospheric blurring limits ground-based instruments to about 1 arcsec of resolution is false; it applies only to long recording times.) Although a 17th-century invention, the filar micrometer became a high-precision tool only in the hands of F W STRUVE in 1820. Since then most double-star positions have been obtained that way, quite close binaries being reached already with the refractors around 1900 (Aitken and others), at least in the northern hemisphere. The southern sky lagged behind until W H van den Bos began his micrometric productivity in the 1920s, and R A Rossiter followed with the discovery of many thousands of fainter pairs.

A modification favored by some observers is the double-image micrometer which uses a birefringent prism.

The four star images produced from a double star are brought into a well-measurable configuration by rotating and shifting the prism.

Photography
During much of the 20th century, photography was the best direct-imaging method in astronomy, but its resolving power was limited by adjacency effects from the chemical processing and by blurring during the fairly long exposure times needed. Extensive double-star data were obtained for wider pairs, typically over 2 arcsec. The long-term photographic monitoring of stars has helped in other ways: with PARALLAX results for nearby binaries, their mass ratios from the orbital shifts of blended images against their centre of mass and sometimes the detection of unseen components from periodic shifts in the motions of stars. Such work could now be done with digitizing cameras (CCDs) which have replaced photographic emulsions in direct imaging.

Interferometry
Owing to high instrumental demands, the original form of interference was little used. A successful variant is the eyepiece interferometer as was constructed and widely used by W S Finsen.

In the last 25 yr a combined high resolution in both angular separation and recording time, now also for modest-size telescopes, has been achieved by 'speckle' interferometry (see SPECKLE IMAGING OF BINARY STARS). It results in superior precision by correlating numerous, very short-exposure images (speckles, tavelures). Most currently used devices consist of microscope optics as objective and collimator, a CCD camera with image intensifier as detector and computers for very fast recording, centering, autocorrelation and processing; colour filters and usually a pair of prisms, to remove atmospheric dispersion in both amount and direction, are added. The full theoretical resolving power at large reflectors, around 0.03 arcsec, can be reached. An important development toward yet higher resolution is the application of long-baseline interferometry (long used in radio astronomy) now at optical wavelengths, as evidenced by results from devices such as the Mark III interferometer.

Space instruments
The Hipparcos satellite measured around 1991 numerous double stars and added some 3000 new pairs, mostly those of larger brightness differences whose detection from the ground was impeded.

Orbits

Apart from their significance for the understanding of stellar origin and of evolutionary patterns, binary stars supply direct determinations of the masses of stars as fundamental quantities. This requires knowledge of their orbits.

Main-sequence stars have a relation between mass M and luminosity L, as expected from theory, because for stars of nearly identical composition the equilibrium conditions governing interior stability make the luminosities and radii dependent only on the mass: L increases with the kth power of M. The exponent k varies along the main sequence, and it also depends on the colours within which the luminosities are defined; for visual magnitudes, $k = 3.8$ for the middle main sequence, but k decreases to about 2.6 for both high- and low-mass (B and M) types.

The apparent orbit of a visual binary as seen in the sky (at right angles to the line of sight) is a parallel projection of the true orbit ellipse. Seven constants, the so-called orbital elements, are needed to describe the motion. Three of them are angles specifying the projection: the inclination is the angle between orbit and projection planes, the node is the celestial direction in which the planes intersect and the longitude of periastron (the point of closest approach of the components, and of fastest orbital motion), counted from the node, gives the orientation of the ellipse. The other elements fix the motion within the orbit: the period (P) in years, the eccentricity, the time of passage through periastron, and the semimajor axis (a) in arcsec. The position in the orbit at any time is then given by formulae which represent Kepler's first and second laws (see KEPLER'S LAWS). There are several computer routines on how to solve for the seven elements as best fitting a given set of observations.

Visual binaries with known orbits (some very precise, others tentative and subject to future revision) now number about 1000. The orbit sizes (a) are mostly under 1 arcsec; the periods range from a few years to some centuries (in cases with well-observed periastron passages up to about 1000 yr), and almost all objects are within 150 pc from Earth. Contrary to the planetary system and to close binaries, orbits of medium or high eccentricities dominate among visual pairs.

To determine the total mass ($M_1 + M_2$), Kepler's third law is used in the form $a^3 = P^2(M_1 + M_2)$ only if a is determined in astronomical units:

$$a \text{ (length in AU)} = a'' \text{ (angular size in arcsec)} \times d \text{ (distance in pc)}.$$

Inaccuracies of distances d cause often the largest uncertainty in the masses. This can be remedied in other ways.

(a) By spectroscopic observations of the orbital motion. Doppler-shift amplitudes alone yield only the one-dimensional radial motion, leaving the orbit inclination and hence the true orbit size and the mass undetermined, but the combination with the visual elements supplies the missing link. The speckle technique in particular has resolved many short-period pairs discovered by spectroscopists.
(b) When the components can be assumed to be main-sequence stars, a mass–luminosity relation can be invoked, along with the known apparent magnitudes, to connect the masses and the distance.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

Cases where this assumption does not hold are revealed by a disagreement between spectral type and the computed mass. Many stars spectrally still classified as main sequence are found to be already evolved in luminosity to above 'zero age' level.

Multiple systems

About a third of binary stars contain at least one additional component. However, the separations are almost always quite different: the ratio of wider versus closer pair is at least 6:1 and often much more. Long-term stability of multiple systems with stellar (not very unequal) masses demands this 'hierarchical' order. So the periods are very different, and there are few visual systems in which both orbits are reliably known.

More common are close spectroscopic subsystems within visual pairs, and there are also cases of definite, periodic deviations from the elliptical motion indicating the presence of an unresolved component. These objects require elaborate analysis since two orbits (14 elements instead of seven) have to be computed simultaneously. Slow changes in the orbits owing to perturbations between components are known in two of them: ξ Ursae Majoris (11182 + 3132) and ζ Cancri (08122 + 1739).

Some noteworthy objects

Within 3 parsec from the Sun, four apparently single dwarf stars and the following three interesting binaries are found.

α Centauri (14396 − 6050), the nearest system, consists of two solar-type stars (masses 1.1 and 0.9) in an orbit of period 79.9 yr, now slowly closing in after maximum separation was reached in 1980, and a red-dwarf companion, a full 13 000 AU distant from the primary pair, but even closer to Earth, hence called Proxima Centauri.

Sirius (06451 − 1643) has a companion with a period of 50.1 yr, which was predicted from periodic changes in the proper motion of the bright star. Resolved in 1862, the companion was found to be almost 10 magnitudes fainter, and the identical white color indicated an enormous disparity of the radii of the stars. It was the first identification of a white dwarf star. (40Eridani B = 04153 − 0739 had been observed long before but its 252 yr orbit with a faint red-dwarf companion and its white-dwarf nature were not known until later.)

LDS 838 (01390 − 1757), a 12th magnitude object with a period of 26.5 yr is one of the lowest-luminosity pairs of red dwarfs. Each component has only 0.12 solar masses; one of them is the very active flare star UV Ceti.

A few other remarkable binaries and multiples may be added.

Castor (α Geminorum, 07346 + 3153) is a sixtuple at a distance of 14 pc. The bright pair has been observed for almost three centuries, and the latest orbit gives it a period of 467 yr. Both components are close spectroscopic binaries with low-mass companions (periods of 9 and 3 days), and the distant 9th magnitude star YY Gem, which belongs to the system, is a unique case of a red-dwarf eclipsing binary (type dM) with a period of 19.5 h.

Capella (α Aurigae, 05167 + 4600), a long-known spectroscopic binary with $P = 104$ days, and at a distance of 13 pc, was resolved and well observed by interferometers and speckle cameras. It consists of two G type giants of nearly equal masses (2.5 solar masses each) and luminosities, evolving synchronously. Also part of the system is a later-discovered, distant red-dwarf pair which may have a period around 400 yr.

The closest pair resolved by a large interferometer is Spica (α Virginis, 13252 − 1110) at a separation of only $0''.0015$, with a period of 4 days.

ε Hydrae (08468 + 0625), at a distance of 36 pc, is of interest because of the diversity of its five known components: a G type and a fainter F type subgiant in a 15 yr orbit, an F type main-sequence star (period about 1100 yr around the primary pair) which is a spectroscopic binary with a low-mass companion ($P = 10$ days), and a still more distant, subluminous dK dwarf star whose period may be around 10 000 yr.

Finally, GC 20393/4 (15102 − 1623) is a faint, wide pair of very old subdwarf stars, separated by 5 arcmin, and 30 pc distant. They race through the solar vicinity at a record speed of nearly 600 km s^{-1} relative to the Sun, or practically at escape velocity within the Milky Way, suggesting an origin in the outer galactic halo. It should be noted that, although separated by at least 10 000 AU, they have kept together on the long trip for twice the age of the solar system.

VLBI (Very Long Baseline Interferometry)

The Michelson stellar INTERFEROMETER was developed by MICHELSON as an optical instrument to measure the angular diameter of stars. In recent times, the method has been extensively used at radio wavelengths, to achieve extremely high angular resolution, greater than that achieved by single-aperture telescopes at any wavelength. The principle is as follows: two RADIO TELESCOPES, receiving a signal from a distant radio source, amplify the signals and send them via transmission lines to a radio receiver. the radio signals arrive at different times at the two radio telescopes, so the shorter path length is lengthened by a delay line that equalizes the time at which the signals are combined by the receiver. If the signals are in phase, they will reinforce one another and the signal amplitude will be twice that of a single telescope (i.e. four times the power). If the signals are 180° out of phase, there will be no signal, since they destructively interfere. If the telescopes are rotating with the Earth, and the time delay is held fixed, the alternating constructive and destructive interference will give a sinusoidal output whose amplitude and phase can be measured. (The optical Michelson stellar interferometer is functionally identical; the radio telescopes are replaced by plane mirrors that send plane waves into a telescope, where they are combined at the focus, where interference fringes are detected.) By extension from the optical case, the sinusoidal radio signal is also called a fringe, even though it is seldom seen directly in modern interferometers. This is because the receiver has, in effect, two channels that cross-correlate the two signals, directly and in quadrature. From the amplitudes of these two outputs, the fringe amplitude and phase are derived.

The great power of the Michelson interferometer lies in its extension to APERTURE SYNTHESIS, in which the signals from an assemblage of many telescopes are combined pairwise. As in so many areas of modern science, the Fourier transform technique is used to derive an image. Given a radio source with a brightness distribution $B(\alpha, \delta)$ on the sky, where α and δ are right ascension and declination, one constructs an approximate Cartesian coordinate system x, y. The distribution $B(x, y)$ has a Fourier dual $b(u, v)$, and it can be shown that the amplitude and phase of the radio fringe from a Michelson interferometer is proportional to the Fourier transform of the source brightness distribution. The dual coordinates (u, v) are determined by the baseline $\boldsymbol{b}_\lambda$, measured in terms of the observing wavelength λ, projected on the sky perpendicular to the line of sight to the radio source. This plane is usually taken with u in the east–west direction, and with v north–south, and is commonly referred to as the uv-plane. A sufficiently large sample of fringe amplitudes and phases, with interferometers sampling many points on the uv-plane, can give a good approximation to the Fourier transform $b(u, v)$ of the brightness distribution, and by numerically calculating the Fourier inversion, the actual brightness distribution $B(x, y)$ can be constructed.

It follows that an array of N radio telescopes, suitably distributed on the Earth, will yield $N(N-1)/2$ pairs, thus allowing one to map radio sources with an instrument having an effective diameter, and a corresponding angular resolution, of a telescope of diameter $D_{\max}$, the length of the maximum interferometer spacing. Such an instrument is called an aperture-synthesis array; the density of Fourier transform samples can be increased by observing as the Earth rotates, thus changing the projected baseline length on the uv-plane. In this case, the technique is known as Earth-rotation aperture synthesis. The VERY LARGE ARRAY (commonly known as the VLA), operated by the National Radio Astronomy Observatory on the Plains of St Augustine, near Socorro, New Mexico, with 27 antennas in a variable-length, Y-shaped array, is a good example of an aperture-synthesis instrument.

Techniques of VLBI

The technique of Very Long Baseline Interferometry, or VLBI, is an extension of Michelson interferometry, made possible by the exquisite control that modern electronics exerts over the time domain. If the transmission lines from the telescopes to the receiver are removed, it is still possible to observe the interference fringes by having a highly stable clock (usually a hydrogen maser frequency standard) at each telescope. The amplified signals are recorded on wide-band magnetic tape recorders (typically at a data rate of the order of 10^8 bits per second or more), using the hydrogen standards for time control. The tapes are then shipped to a central processing facility, where the received signal is now a string of discrete samples $e(t_i)$ at known times t_i. The two data streams are then cross-correlated numerically, giving the fringe amplitude and phase. (For a general treatment of interferometry, including VLBI, see Burke and Graham-Smith (1997).)

Several VLBI arrays are in operation: the VLB Array (VLBA) of the National Radio Astronomy Observatory with its processor in Socorro NM, the European VLBI Network (EVN), with a processor in Dwingeloo, Netherlands (see JOINT INSTITUTE FOR VLBI IN EUROPE), and the Southern Hemisphere Array, with its processor in Narrabri, NSW, Australia. There is also a worldwide network, a collaboration among the above VLBI arrays with the addition of other national radio telescopes.

The VLBA can be taken as an example of a dedicated VLBI system. It consists of ten similar radio telescopes spread across the USA and its outlying territories; the array is bounded by telescopes in St Croix, US Virgin Islands, on the southeast, Hancock NH on the northeast, Brewster WA on the northwest, and Mauna Kea HA on the southwest, with a maximum baseline of 10 000 km. At the present time its shortest operating wavelength is 7 mm, giving a maximum angular resolution of about 150 microarcseconds. The operating wavelength can be switched rapidly from one band to another, and the observing schedule, sent out to the individual telescopes

some time in advance, includes the time and duration of observation the source to be observed, and the frequency band.

There are some practical considerations that arise when making VLBI observations. The masers at the individual telescopes will have slightly different frequencies, and therefore the time base on each magnetic tape will have systematic errors, showing up as time differences and differences in fringe rotation. The VLBA correlator, therefore, performs the cross-correlation for a number of different time delays and fringe rotation rates, in order to correct for these differences. In the case of a 'hard-wired' interferometer such as the VLA, timing variations occur, and these are usually corrected by observing a nearby calibration source and deriving the necessary corrections. For VLBI observations, this is sometimes possible, but in many cases it is not feasible to do so. For an array of several telescopes, however, there are closure relations that allow extra information to be derived. If three telescopes are observing the same source, there is a sum condition on the three fringe phases that gives useful phase information, and there is a condition on the fringe amplitudes, when observing with four telescopes, that gives useful constraints on the individual amplitudes. When an array of ten telescopes is used, as in the case of the VLBA, there is enough redundancy in the various combinations to constrain the uncertainties in the Fourier transform, giving maps of remarkable fidelity.

Science applications of VLBI

There is a surprising variety of scientific problems that can be addressed by the methods of VLBI. Quasars and the nuclei of active galaxies (BL Lac sources, radio galaxies and Seyfert galaxies) all have structures in the milliarcsecond range or smaller. Pulsars and gamma-ray burst sources are even smaller, requiring baseline lengths far longer than anything currently feasible, Molecular maser sources are also of milliarcsecond size, and these occur in association with star-forming regions and cool, evolved stars such as the Mira variables. Three general classes of observation can be identified: the mapping of milliarcsecond structures, the measurement of relative source positions to achieve higher astrometric accuracy, and the use of known sources as references to study geophysical phenomena such as continental drift and polar wandering.

Active galactic nuclei

The detailed study of ACTIVE GALACTIC NUCLEI (AGNs) has shown that the jet-like structures seen on large scales persist at the smallest angular scales that have been studied. Paradoxically, the (relatively) long radio wavelengths are closely related to phenomena at x-ray wavelengths. The radio phenomena observed by VLBI are in large measure relativistic, since the radio waves are generated by synchrotron radiation from relativistic electrons circulating in magnetic fields. A large fraction of the sources involve massive black holes, surrounded by accretion disks (the hot gas in these accretion disks, observed at ultraviolet and x-ray wavelengths, is in the process of spiralling down into the black hole at the center). The exact process is still unclear, but seems to involve magnetic fields in the accretion disks, twisted by differential rotation in the disks, ultimately releasing enormous amounts of energy by accelerating electrons to relativistic energies and confining the particles to a narrow jet. Shortly after VLBI was developed, it became clear that rapid changes were developing in the structure of the jets, and it is now well-established that the jets exhibit apparent motions that significantly exceed the speed of light, sometimes by an order of magnitude. Although the structure of fundamental physics might be questioned, such a dramatic revision as superluminal velocity does not seem to be needed. The effect is almost certainly caused by the aberration effects observed when a relativistic beam is directed at the observer. The effect requires a beam of particles having bulk motion close to the speed of light, directed within a few degrees of the observer.

A relativistic effect that must be considered in conjunction with these compact, relativistic sources of SYNCHROTRON RADIATION is the self-Comptonization of the radiation. As the sources increase in energy density, there can be so many radio photons generated that they are Compton-scattered by the electrons and become x-ray photons, which can be observed by X-RAY TELESCOPES. This has the effect of limiting the possible surface brightness at radio wavelengths; expressed in terms of 'brightness temperature' (the temperature a source would need to have at the observing band to give the observed specific intensity, not a physical temperature necessarily). As a consequence, it is not possible for a synchrotron source to exhibit a brightness temperature in excess of 10^{12} K. Unfortunately, it is not possible to verify this prediction by interferometer baselines on Earth. The flux of a RADIO SOURCE is proportional to the product of its average surface brightness and its angular size, and the wavelength dependences cancel out. At any wavelength, therefore, an interferometer with a baseline length of an Earth diameter, observing even the strongest radio source, can only set a limit of 10^{12} K on the surface brightness of the compact structures.

This limitation to our knowledge can be overcome by using interferometer baselines that exceed the diameter of the Earth. By placing a VLBI telescope in space, there is in principle no limit on the angular resolution that might be achieved. It has turned out that the technical difficulties can be overcome; a successful demonstration was carried out, using the TDRSS (a data relay satellite system), that showed the practical feasibility of such measurements. This was followed up by HALCA, a dedicated VLBI satellite launched by the Japanese Space Institute ISAS in February 1997. The results are clear: a large fraction of quasars and AGNs have radio nuclei that exceed the self-Compton limit.

Maser sources

The extragalactic maser sources have been another major object of VLBI research. The lambda-doublet lines of the hydroxyl radical at 1612, 1665, 1667 and 1720 MHz all exhibit high surface brightness (10^{10} K or more) that can only be a consequence of gas clouds being pumped by radiation or by collisions to invert the level populations, resulting in a one-pass maser that can amplify the background radiation. The same phenomenon occurs in the rotational lines of water, silicon oxide and methanol that are accessible in the radio spectrum. Star-forming regions frequently have many such maser sources, as do a wide variety of evolved stars. In such cases, the difficulty in determining the fringe phase can be overcome by self-referencing: a particular compact line feature can serve as a reference within the maser complex, and the positions of other line sources, often separated in Doppler shift by several km s^{-1}, can be measured with respect to the reference maser.

Megamasers

Extragalactic maser sources have also been discovered. These are referred to as 'megamasers' since the necessary energies are so high. One of the best studied of these, the megamaser in the active galaxy NGC 4258, appears to be emitting 300 solar luminosities in the 22 GHz water line. The line structure turned out to be extraordinary: there was a complex of strong central lines, having very little velocity relative to that of the galaxy, but in addition there were satellite maser lines with relative Doppler velocities $\pm$900 km s^{-1} to either side of the central complex. A detailed analysis of the VLBI-derived map showed that the velocities could be accurately explained by a simple model. A ring of gas surrounds the (presumed) black hole at the center, and we see the ring nearly edge-on. The central line complex changes linearly in Doppler velocity across the source, and is amplifying the radiation from the central source; this allows the acceleration of the molecular gas to be measured. The high-velocity lines come from masers at the terminus of the edge-on ring, and these allow the Keplerian velocity to be determined. The result is firm evidence of a central black hole having a mass of 70 million solar masses (see Miyoshi *et al* 1975, Herrnstein *et al* 1999).

Voids

Galaxies have a strong tendency to cluster. They have been drawn together by mutual gravitational attraction. Seventy per cent of galaxies are found in groups or clusters that are probably gravitationally bound. In turn, the groups of galaxies lie along filaments that interconnect. The largest clusters of galaxies tend to be found at the intersections of several filaments. Even the 30% of galaxies that are not in bound groups lie, almost entirely, within the filaments.

The filaments occupy only a small fraction of space. Most of space has no observable matter. These empty regions are the '*voids*'.

The discovery of voids

Although the general tendency for galaxies to cluster was known for a long time, the extreme segregation of galaxies into a small fraction of the available volume was not appreciated until recently. With information about the distribution of objects on the plane of the sky augmented by only crude information about distances from galaxy sizes and magnitudes, there is too much confusion from projection overlay to get a good sense of structure. It is necessary to have the REDSHIFTS of galaxies in order to place them in distance and, hence, to be able to construct a three-dimensional map of the distribution of galaxies (see DISTRIBUTION OF GALAXIES, CLUSTERS, AND SUPERCLUSTERS). Only in 1978, with galaxy redshifts in hand, did Stephen Gregory and Laird Thompson comment that there were regions nearly devoid of galaxies to the foreground of a supercluster that extends from the Coma cluster to the cluster Abell 1367. Several other empty regions were found within the next few years and, in 1981, the instantly famous Boötes void was reported by Robert Kirshner, August Oemler, Paul Schechter and Stephen Shectman. This void extends over roughly a million cubic megaparsecs (30 million cubic light-years).

Over the years since, there have been searches to see whether there is anything to be found in the Boötes void. A few small galaxies have turned up. Still, it is an empty place. The Boötes void may not even be the biggest empty region within the currently accessible universe. It is distinctive in part because it is surrounded by the prominent supercluster domains of Hercules–Corona Borealis, Leo and Ursa Major. There are even larger regions of substantial underdensity. The larger regions are hard to characterize because they extend so far across the sky that they become lost in the obscuration of our Milky Way Galaxy and they extend so far in distance that redshift surveys become incomplete.

Nearby voids

There is no need to go far to find a void. The Milky Way Galaxy is part of the LOCAL GROUP which in turn is part of the Coma–Sculptor cloud, a filament that lies in the equatorial plane of the Local Supercluster. In the plane of this filament there are galaxies in all directions and to the south of this plane in supergalactic coordinates there is anther filament. However, to the north of this plane, just beyond the last galaxies of the Local Group, is the Local Void. This empty region is poorly surveyed because it is intersected by the Milky Way. However, there are few nearby galaxies on either side of the Galactic plane over a wide segment of the sky.

There are several voids that are somewhat farther away but better studied because they cover a restricted part of the sky and stand out with good contrast against pronounced filaments. The Perseus–Pisces filament is particularly well defined, at a distance of 60 Mpc (200 million light-years). Immediately to the foreground is a large region devoid of galaxies.

The topology of voids

The complement of voids are the superclusters and figure 1 in SUPERCLUSTERS AND THE LOCAL SUPERCLUSTER illustrates both the filamentary nature of the distribution of galaxies and the voids. The filament–void network can be compared with a sponge. The material of the sponge can be equated with the filaments and the sponge holes with the voids. The sponge material is all interconnected, else the sponge would fall apart, but also the holes are all interconnected, so water can pass through. However, with this analogy, the universe is a very tenuous sponge with frail material connections and big holes.

The universe must have begun with only minute density variations. Over time, matter has gathered through self-attraction in the high-density regions and evacuated the low-density regions. Hence, even in co-moving coordinates the domain of the voids has been growing. In metric coordinates, the voids are much bigger now than in the past. It follows that matter is moving away from voids, toward high density concentrations.

There is still debate about how much residual matter there is in voids. Galaxy formation may only occur above a certain density threshold which leaves open the possibility that there could be a considerable amount of total mass tenuously spread through the voids. Stringent limits are set by failure to detect intergalactic gas over a wide range of temperatures. The only hint that there might be residual gas comes from studies of absorption lines in distant quasars. These absorption lines arise from tenuous intergalactic gas in the foreground of the quasars. However, at low redshifts (the present epoch) there are relatively few absorbing gas clouds and it remains to be demonstrated whether that gas is associated with the intersection of filaments with the line of sight or with voids.

Volans

(the Flying Fish; abbrev. Vol, gen. Volantis; area 141 sq. deg.) a southern constellation which lies between Mensa and Carina, and culminates at midnight in mid January. It was first shown on Petrus Plancius' celestial globe of *c*. 1598 as Piscis Volans, though it is usually attributed to the Dutch navigators Pieter Dirkszoon Keyser (also known as Petrus Theodorus) and Frederick de Houtman, who charted that part of the southern sky in 1595–7.

A small, inconspicuous constellation, the brightest stars in Volans are β Volantis, magnitude 3.8, γ Volantis, a binary with yellow (G8) and pale yellow (F2) components, magnitudes 3.8 and 5.7, separation 14.11″, ζ Volantis, magnitude 3.9, and δ Volantis and α Volantis, both magnitude 4.0. Another interesting star is ε Volantis, a double with bluish-white (B6 and B9.5) components, magnitudes 4.4 and 7.5, separation 6.0″, that have the same proper motion, the former of which has an unseen companion that revolves around it in 14.17 days.

There are no bright star clusters, nebulae or galaxies in the constellation, the brightest being NGC 2442, an eleventh magnitude barred spiral galaxy.

Volcanism in the Solar System

Volcanism is the main endogenous process (a process originating within the planet) which gives PLANETARY SURFACES most of their characteristic features. Volcanism consists of the superficial outflow of liquid mixed with a variable quantity of gas and crystals, which comes from the PLANETARY INTERIOR. These liquids are produced by the melting of the planet's or satellite's interior. They are called 'lava' or 'magma' and come up to the surface owing to buoyancy forces. Water and hydrocarbon springs on Earth are not part of these magmatic liquids.

Volcanism not only modifies the structure and the morphology of the planetary surface. During and just after the formation of planetary bodies, accretional heating partially separated volatile from refractory elements, degassed the mantle and produced primitive atmosphere. Volcanism causes this degassing of the mantle to continue, and it is gradually modifying both the planetary interior and the atmosphere.

The morphological types of volcanic features strongly depend on the magma viscosity and gas content. Very-low-viscosity magma induces flat lava flows and may produce lava plains in the case of abundant flooding. An increase in the viscosity produces shield volcanoes with shallow sloping flanks (inclined at about 10º) for intermediate-viscosity lava or domes with steep peripheral flanks (inclined at about 25º) for high-viscosity lava. A significant gas content fragments the magma during volcanic explosions and produces fragments of rock called 'tephra'. During low-energy explosions, the tephra again fall around the outflow points, forming scoria or cinder cones. High-energy explosions cover large areas with ash or pyroclastic deposits expelled aerially from a vent. Some volcanoes may produce continually the same magma with the same gas content that produces monogenic volcanic construction (built up by one kind of eruption). Elsewhere, the gas content and the magma viscosity may change during a single eruption or throughout the volcano's history, inducing a complex polygenic volcanic construction (built up by several kinds of eruption).

Volcanism timing allows the distinction between three kinds of worlds: (1) active worlds, with present evidence of endogenic activities, (2) recently active worlds on which active resurfacing processes have occurred on a large scale after the end of the heavy bombardment, but which now seem dead, and (3) dead worlds, on which the majority of the surface pre-dates the end of heavy bombardment and where the geological activity has occurred only occasionally after the end of this bombardment.

Two types of solid planets and satellites exist in the solar system. There are silicated and rocky bodies in the inner solar system and icy bodies in the outer solar system. Io and Europa, two Galilean satellites of Jupiter, are silicated bodies, although they belong to the outer solar system. Volcanism exists on almost all of these bodies.

Volcanism in the inner solar system

Active worlds

The Earth (diameter 12 750 km), the basis for planetology. Volcanism on Earth has been studied considerably since Pliny the Younger died studying the famous eruption of Vesuvius in AD 79. Terrestrial volcanism is the reference for comparative planetary volcanism studies, and the definitions of rocks, eruptions and feature types were proposed on Earth.

The geographical distribution of volcanoes on Earth is one of the characteristics of our planet. About 95% of active volcanoes are grouped together and form volcanic lines. The first group is located on the islands or mountains near oceanic trenches around the Pacific and near Indonesia and the West Indies. This volcanism is mainly andesitic (SiO_2 55%), basaltic (SiO_2 50%) and rhyolitic (SiO_2 60%). The second group lies under oceans, on the top of oceanic ridges. This volcanism is basaltic (SiO_2 50%). The location of these two volcanic types is strongly correlated with the global dynamics of the EARTH'S INTERIOR (plate tectonics). Volcanism mainly occurs near plate boundaries. The other 5% of volcanoes are isolated volcanoes, spread over ocean floors or continents. These volcanoes are basaltic ones and are called 'hot spots'.

The popular notion of the Earth's interior is a world-wide layer of magma beneath a solid thin shell. Following this notion, volcanism is simply the arrival of magma through a hole or a fracture crossing the crust. This popular notion is totally false. The Earth is divided into three levels: the superficial crust 5–40 km thick, the mantle from the base of the crust to 2900 km and the core from 2900 km to the centre of the Earth. The Earth is entirely solid with the exception of the outer core, which is made of molten iron. This liquid outer core represents less than 15% of the Earth's volume, 2900 km below the surface, which is not directly involved in volcanism. The Earth's interior is solid, but hot, with a temperature of up to 5000 ºC. This heat is generated by natural radioactive decay. The solid state of the Earth despite this high temperature is due to the very high pressure created by the weight of overlying rocks.

Temperature differences between the cold superficial layers and the hot interior produce density differences and enormous buoyancy, circulatory and convective forces. Impelled by these convective forces, the solid mantle flows very slowly like ice in a glacier. These mantle motions induce superficial motion of the cold superficial layers, called continental drift or plate tectonics. Downward-flowing superficial oceanic rocks

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

introduce oceanic water deep into the mantle. This water lowers the melting point and produces a small proportion of molten material. Upward-flowing mantle reaches a level where the drop in pressure allows a small proportion to melt. If enough is formed, the formed magma rises away from the denser residue of solid infusible rocks, owing to buoyancy forces. On Earth the convective cells are more than 1000 km wide; the upper parts of these cells are the tectonic plates with only horizontal motion. Volcanism occurs at the plates' boundary where upwards or downwards motions exist and induce a partial melting of the mantle. Some other circulatory motions exist inside the mantle, with localized upward flows of solid mantle. These localized upward flows which induce localized drops in the pressure, partial melting and volcanoes, and are far from the plates' boundaries, are called 'hot spots'.

In 2001, a NASA mission to study Alaska's unique terrain provided scientists with their first detailed look at the changing topography of one of Earth's most active volcanic regions. Researchers at the Alaska Synthetic Aperture Radar Facility, Fairbanks, created a high-resolution digital elevation model of Umnak Island, home to the Okmok volcano. This model can be used to produce new, accurate geologic maps. The most recent topographic map of the region was made in 1957 from aerial photographs. Okmok has erupted four times since then, dramatically changing the landscape. The Alaska scientists used data gathered in October 2000 by the NASA/JPL Airsar instrument, a side-looking imaging radar system carried aboard a NASA DC-8. It collected the Alaska data as part of its PacRim 2000 Mission, which took the instrument to French Polynesia, American and Western Samoa, Fiji, New Zealand, Australia, New Guinea, Indonesia, Malaysia, Cambodia, Philippines, Taiwan, South Korea, Japan, Northern Marianas, Guam, Palau, Hawaii and Alaska. Researchers there combined numerous Airsar strips of data into a mosaic, fused it to Landsat imagery, checked its accuracy and generated a number of data products, including the mosaic of Umnak Island.

Venus (diameter 12 102 km) (figure 1). There is no doubt that volcanism has been responsible for the generation of the majority of the Venusian surface. The Venusian surface is affected by only few impact craters, indicating a geologically young age. Venusian plains exhibit long flow-fields, with long lava channels in some places. Many thousands of volcanoes exist on Venus, either on plains or in the highlands (see VENUS: SURFACE). The MAGELLAN pictures revealed 550 concentrations of small volcanoes <20 km in diameter, 270 intermediate volcanoes between 20 and 100 km in diameter with a great variety of morphologies, 150 large volcanoes in excess of 100 km in diameter, 80 caldera-like features and more than 100 steep-sided domes sometimes called 'pancakes'. Some strange volcanic features without equivalents on Earth or other planets exist on Venus. There are complex overlaps of bulges, faults, cinder cones and lava flows, and they are called '*coronae*', '*arachnoids*', '*novae*'…. The majority of these volcanic features are consistent with basaltic composition, a hypothesis confirmed by the findings of Soviet landers whose soil analyses are chemically similar to those of basalt (SiO_2 50%). The steep-sided domes may represent more silicic magma (SiO_2 60%), while lava channels may represent ultramafic lava flows (SiO_2 45%). Only a little evidence was found for extensive pyroclastic deposits.

The volcanic features show a broad global distribution, in contrast to the distribution of volcanoes along plate boundaries on Earth. Some highlands show an excess of volcanic features, while some lowlands show only lava floods.

There is no direct evidence in the Magellan data for current volcanic activity. Some atmospheric analyses have shown sulfur dioxide variations, which may be due to volcanic activity. However, the dynamics of the atmosphere may also explain these observed variations. Crater counts would indicate that the whole Venusian surface is younger than 0.8–0.5 Gyr. An equilibrium resurfacing model for explaining the impact craters' density implies a current volcanic lava flux of $0.5\ km^3\ yr^{-1}$, a value comparable with the terrestrial intraplate volcanism. Thus there is hardly any doubt that, as is the Earth, Venus is a geologically active planet despite the lack of active eruptive processes identified during the Magellan mission.

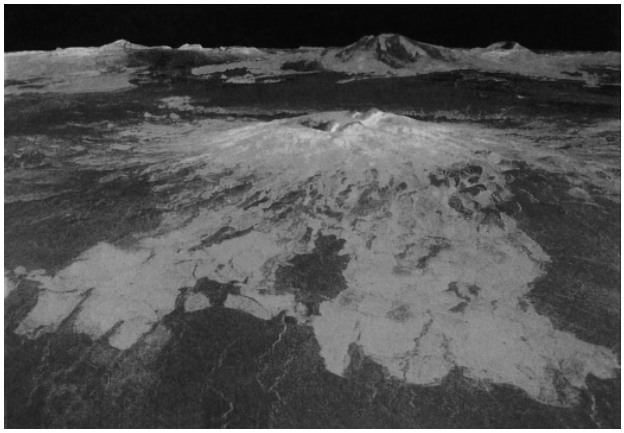

Figure 1. A volcano on a rocky body: Sapas Mons on Venus. Sapas Mons is 400 km across and 2 km high. It is a typical shield volcano. The sides of the volcano are covered with numerous overlapping lava flows which appear clear in this image. This volcano looks like Hawaiain volcanoes or large Martian volcanoes. No impact craters are visible on this picture, which indicates a very young age for the Venusian volcanism. This three-dimensional perspective view is produced with radar data from Magellan (NASA).

The density of Venus indicates that the Venusian interior is theoretically more or less similar to the Earth's interior. On Venus, mantle convection produced and still produces superficial motions and tectonic features, which are different from plate tectonics. The volcanism distribution confirms that the global dynamics of Venus's interior is quite different from that of the Earth. The localized 'hot-spot-like' convection strongly dominates the plate-tectonics-like convection. The origin of this difference is poorly understood.

Recently active worlds

Mars (diameter 6794 km). Volcanoes are unquestionably on Mars (see MARS: SURFACE). Four enormous shield volcanoes and many smaller ones rise 15–25 km above the surface. These volcanoes are mainly located on a 8000 km wide broad topographic bulge which stands about 10 km high. OLYMPUS MONS, the largest volcano in the known solar system, rises 26 km above the surrounding plateau. These volcanoes possess nested summit calderas and have numerous lobate lava flows on their flanks. Other smaller shield volcanoes exist in other places. Low-relief shields with irregular summit craters and numerous radial flows on their flanks are called 'paterae'. Some domes (called 'Tholus') and cinder cones have also been identified across Mars. Volcanic plains with multiple overlapping flow lobes are found around the periphery of the shield volcanoes. The complex flows can extend for >1000 km beyond the shields. Large plains covering wide areas in the northern hemisphere (but rare in the southern hemisphere) have controversial origin. The preferred origin is a volcanic one, based primarily on morphological similarity to lunar maria. No or only little evidence was found for extensive pyroclastic deposits.

In 1976 and 1997, respectively, the two VIKING landers and MARS PATHFINDER made *in situ* chemical analyses of soil and rocks. These analyses are consistent with volcanic rocks (mainly basalts, and one andesite-like analysis). Some meteorites (the SNC METEORITES) are supposed to have a Martian origin. These meteorites are mainly volcanic rocks (basalts and pyroxenites).

Volcanism existed on Mars from the earliest epoch, the lower Noachian, to the latest one, the upper Amazonian. The maximum of visible volcanic materials was produced during the Hesperian (from 3.5 to –2 Gyr). The younger volcanoes, Olympus and Arsia Mons, are estimated to be near 0.5±0.25 Gyr.

The Martian interior is theoretically more or less similar to the Earth's interior. On Mars, mantle convection produced superficial motions and tectonic features which are different from plate tectonics. The lack of active volcanoes since 500 million years ago indicates that the mantle convection now is either very low or has completely stopped. In the past, the mantle convection was active, and looked like hot-spot-like convection rather than plate tectonics convection.

Dead worlds

The Moon (diameter 3476 km figure 2). On the MOON, 84% of the surface which was called 'terrae' by GALILEO in the 17th century consists of old anorthositic cratered crust. However, about 16% of the surface consists of younger flat basaltic plains and flows which fill the old low-lying basins and form black patches on the Moon's face. These plains were called 'maria' by Galileo. The lava flows inside the plains are very long (up to 1000 km) with very low slopes (less than 1º), a factor that indicates a very low viscosity for the lava, with very low gas content. Many of these flows present sinuous rilles, which may be interpreted as collapsed lava tubes or erosional features caused by very hot lava flows. The thickness of lava may reach 10 km under Mare Imbrium. A very few cinder cones, shield volcanoes and volcanic domes rise up from the lava flows. The majority of maria are located on the near side.

This volcanism became evident during the waning stage of heavy bombardment which occurred before –3.9 Gyr. The volcanism was important from –3.9 to –3.5 Gyr, then decreased and virtually stopped 3 Gyr ago. The larger maria fill very old impact basins, but the superficial flows are some hundreds of millions of years younger than the impact itself. The maria are more abundant on the nearside than on the farside. Apollo samples indicate that lunar lava chemical composition is relatively similar to that of terrestrial basalts.

Figure 2. A lava plain on a rocky body: Mare Serenitatis (left) on the Moon. White mountains (on the right) are 'terrae'. No visible volcanic structures are seen inside this part of Mare Serenitatis, which only consists of very flat lava flows. Numerous small impact craters are visible on the mare, because the lava flows are 3.5 Gyr old (NASA–Apollo).

On the Moon, volcanoes ceased 3 Gyr ago. The dynamics of the lunar mantle during these very old epochs is poorly known. It is only known that this volcanism was not accompanied by significant tectonic motions, contrary to the Earth, Venus and Mars. Volcanism is more abundant on the nearside than on the farside, because the crust thickness is more significant on the farside, and the buoyancy forces seldom allowed the magma to reach the surface. There is a geographical relation between volcanism and large impact on the Moon, but genetic relationships are not clear because of the large chronological interval between large impacts and maria flooding.

Mercury (diameter 4878 km). On MERCURY, maria-like plains called 'smooth plains' are probably volcanic in origin. Unfortunately, the modest resolution of MARINER 10 images makes it difficult to clearly identify volcanic features. These smooth plains are mainly inside and around CALORIS BASIN, the major impact basin of Mercury. These smooth plains cover large areas of relatively ancient 'intercrater plains' which are possibly volcanic plains flooded during the heavy bombardment.

Crater chronology would indicate that the maximum of smooth plain flooding is geologically contemporaneous with the Caloris impact. The end of volcanism probably occurred 3.5 Gyr ago.

The dynamics of the Mercurian mantle during these very old epochs is poorly known. As on the Moon, it is only known that these periods of volcanism were not accompanied by significant tectonic motions, in contrast to the Earth, Venus and Mars. There is a geographical and a chronological relation between volcanism and large impacts on Mercury, suggesting genetic relationships such as a pressure fall in the mantle under the Caloris cavity.

The meteorites' parent bodies and the asteroid belt. About 8% of the catalogued METEORITES are volcanic rocks, mainly basalt or pyroxenite. There are five main kinds of these volcanic meteorites and they are called eucrite, howardite, aubrite, diogenite and urellite. The meteorites are suposed to be Earth-crossing fragments of asteroids. Thus, some ASTEROIDS with past volcanic activity exist in the asteroid belt. Some asteroids have a spectral signature of volcanic rocks. VESTA is supposed to be the diogenite and eucrite parent body, and Nysa is supposed to be the aubrite parent body. Radiochronological dating of volcanic meteorites indicates that the volcanism in the asteroid belt occurred only 10–100 million years after the formation of the solar system.

The relationship between the duration of volcanism and planetary size

After the end of ACCRETION, the heat inside a planet is mainly produced by radioactive decay. This heat production by massive bodies is supposed to be the same for all the silicated bodies and identical to the chondritic heat production value (about 10^{-11} W kg^{-1}). This heat production inside the planets' interior balances the heat lost to space. This balance fixes the interior temperature. If the loss is efficient with regard to the production, the temperature is low; if the loss is not efficient, the temperature is high. The heat is produced inside the planet and is related to its volume; the heat is lost by the surface. This balance is thus regulated by the volume/surface ratio, which is proportional to the planetary radius: a small planetary body with a low volume/surface ratio has efficient heat loss and a low internal temperature ; this is the case now for the Moon, Mercury and the asteroids. A large planetary body with a high volume/surface ratio has inefficient heat lost and a high internal temperature ; this is now the case for Venus and Earth. An intermediate planetary body has an intermediate volume/surface ratio and has an intermediate internal temperature; this is the case for Mars today.

At the beginning of their history, all the planetary bodies were hot because of the accretional heating and the short-lived radioactivity. After the end of this primeval heat production, the heat production was mainly due to long-lived radioactive elements (K, U, Th). When considering the solution to the spherically symmetric heat equation, the accumulation of heat from long-lived radionuclides produces a maximum in temperature after several hundred million years in large bodies. This has been confirmed by the extensive magmatic phase on the Moon which started 500 million years after its formation. After this maximum in temperature, because of the natural decay of radioactivity, there has been a secular cooling for all the planetary bodies. This cooling has induced a gradual stoppage of volcanism, with end times related to size and volume/surface ratio of the planets: this stoppage occurred very early for the small bodies (the meteorites' parent bodies), 1–1.5 Gyr after the accretion of Mercury and the Moon, 4 Gyr after the accretion of Mars and has not yet occurred for Venus and the Earth.

Volcanism in the outer solar system

In the outer solar system, where the temperature is 100 K, one planet (Pluto) and almost all large satellites have a low density ($\leq$2 g cm^{-3}) and water ice spectral reflectance. This indicates that water ice is a major component of these bodies, with a proportion larger than 50%. Other volatile compounds (N_2, NH_3…) may be mixed with water ice. These bodies are called icy bodies. Only two satellites of Jupiter, Io and Europa, have a density >3 g cm^{-3} and are mainly rocky bodies.

Io, Europa and tidal heating

Io (diameter 3630 km, figure 3) is one of the four Galilean satellites of Jupiter. Its density of 3.55 g cm^{-3}

Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

indicates a global composition of silicates and iron. Io's surface displays a wide variety of colors and spectra which are dominated by sulfur compounds. Io's surface geology is dominated by volcanic vents, craters, fissures, flows and other morphological forms attributed to volcanic processes (see also IO: VOLCANISM AND GEOPHYSICS). Active plumes of volcanic material reaching heights of 300 km were seen by Voyager and GALILEO MISSION spacecraft in 1979 and 1997. These plumes are thought to be driven up by SO_2 or sulfur vapors. Sulfur compounds are certainly present on the surface, but, because of the low viscosity of solid sulfur, the heights of mountains, 9000 m, indicate a dominantly silicated composition for high mountains. Temperatures >1500 ºC measured by Galileo above active volcanoes prove the existence of molten silicates. It is not known whether low topography lava flows are composed of pure sulfur or sulfur rich silicates.

New large volcanic deposits and flows were seen by the Galileo spacecraft 18 yr after the Voyager fly-bys. No impact craters can be seen on Io's pictures, an observation which indicates that the volcanism is a very active resurfacing process. The global average height of Io's resurfacing is about 100 m $(10^6 \text{ yr})^{-1}$.

Io's volcanism supplies a very thin atmosphere (10^{-2}–10^{-7} Pa). Around Jupiter, a plasma torus is a result of material escaping from Io (see also IO: PLASMA TORUS).

Io is a small planetary body, with theoretically not enough radiogenic heating to be active now. However, Voyager revealed that Io is the most active solid world in the solar system. Another heat source other than radiogenic heating must be present for Io. The orbit of Io has a measurable forced eccentricity, which is particularly pronounced because of the phenomenon of orbital resonance with Europa and Ganymede. The result of this forced eccentricity is that Io's tidal bulges are continually flexed and moved with respect to Io's interior. The tidal bulge is about 7 km in height, and its periodic flexion is ±100 m. This is a significant source of friction and of tidally generated heat. In the case of Io, heat generated by tidal dissipation (about 10^{14} W, corresponding to 10^{-9} W kg^{-1}) is probably 100 times the rate of radiogenic heating. This is enough to melt at least some parts of Io's interior.

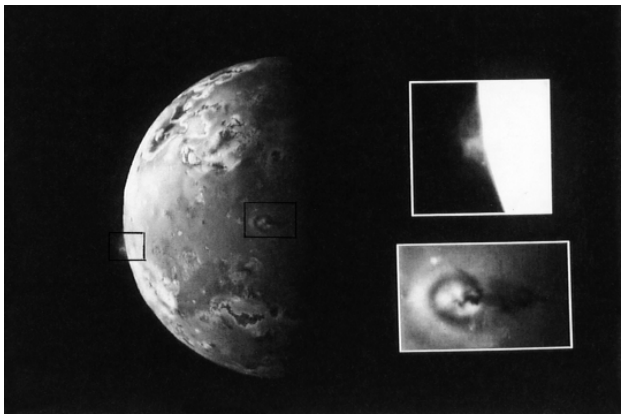

Figure 3. Global view of Io, showing numerous lava flows, and two active plumes: one on the limb (right) and the other on the terminator (left). These two plumes are about 200 km high. Detailed views of these plumes are shown on the right. Note the shadow of the plume located near the terminator (NASA–Galileo).

EUROPA (diameter 3138 km) is a satellite of Jupiter, 3.04 g cm^{-3} in density. This density indicates a silicated composition. It may be briefly described in this section even though its visible surface is completely covered by water ice. Density calculation and modelling indicate a silicated sphere of radius 1400–1500 km, surrounded by a 100–150 km thick H_2O layer. Voyager and Galileo images revealed geologically active or recent resurfacing processes bringing liquid water or ice-crystal mush to the surface. The 100–150 km thick H_2O layer is probably not completely frozen, and a liquid water ocean is probably overlain by an ice field. The flooding of liquid water on the surface does not correspond to volcanism *sensu stricto*, but rather to polar-like phenomena. The H_2O layer is probably warmed at the H_2O–silicate boundary by volcanism, similar in origin to Io's volcanism, but with a lower intensity.

The icy bodies

The surfaces of 13 of these icy bodies larger than 450 km in diameter have been well imaged by Voyager and Galileo spacecraft. On these kinds of bodies, volcanism may bring to the surface the molten compound of the interior: liquid water. The morphology created by this water volcanism is very different from that of their silicated counterparts. Fractures, vents and dykes may exist, but volcanic morphologies similar to the popular notion of volcanoes do not exist. On many satellites (Ganymede, Enceladus, Miranda, Triton), the surface of resurfaced ice is affected by sets of parallel or crosscutting ridges and grooves, poorly understood in origin, despite their frequency in the solar system.

Active worlds: Enceladus (Saturn's satellite) and Triton (Neptune's satellite). ENCELADUS (diameter 500 km) displays two different terrain units: old heavily cratered terrain units, cut and overlain with smoother units closest in morphology to bright grooved or smooth terrains of GANYMEDE. There are essentially two types of grooves on Enceladus: Ganymede-like sinuous grooves, which may have the same origin (extruded and ridged low-viscosity fluid, probably liquid water or a mush of water-ice crystals), and straight grooves generally interpreted as tensional or volcanic fissures. The grooved and smooth terrains of Enceladus have no detectable impact craters,

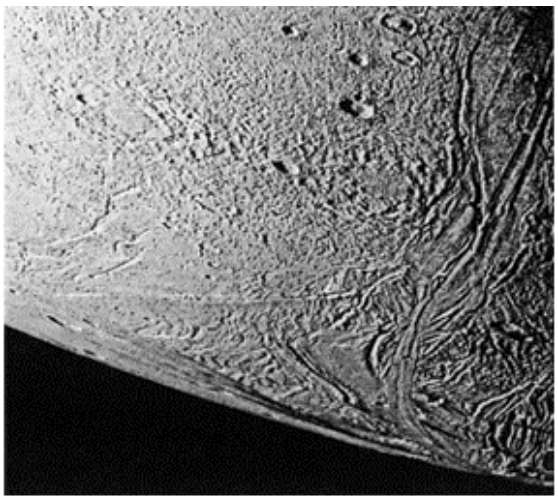
Copyright © Nature Publishing Group 2002
Brunel Road, Houndmills Basingstoke, Hampshire, RG21 6XS, UK Registered No. 785998
and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS1 6BE, UK

which implies a very young age, of less than a few hundred million years. The albedo of Enceladus is uniform and virtually equal to 1. Analysis of the way the surface scatters light suggests that it is covered by fresh ice frost. A likely cause of this is a deposit of frozen spray from young volcanic eruptions perhaps continuing on Enceladus up to the present day. Another argument in support of the present dispersion of spay from Enceladus is that Enceladus orbits in the middle of the E ring, which consists of spherical particles about 1 μm in size. Such small particles would not survive more than ten thousand years in the interplanetary medium, suggesting that active volcanism from Enceladus is at the origin of the E ring.

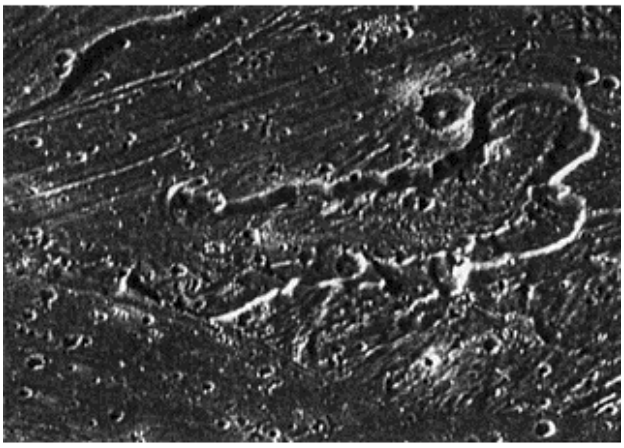
TRITON (diameter 2720 km) is the largest satellite of Neptune. The entire visible surface is crater poor and relatively young. The older terrains (the hummocky and the cantaloupe terrains) show volcanic evidence: flow-generated terrains containing a variety of domes and ridges which appear to be viscous extrusions which have erupted along the fault lines. These older terrains are overlain with smooth plains, which in some places form full flat-floored depressions 200 km wide. These younger terrains seem to have been formed as a series of large-volume, viscous flows. In the center of the flat-floored depressions is a collection of pits and flows, which may be the site of the most recent volcanic activity. The southern part of Triton is covered by a polar cap probably made of frozen nitrogen. In 1989, two active plumes were seen by Voyager inside the polar cap. Each plume sends a jet of dark material upwards to an altitude of 8 km and produces dark deposits. Triton is the only icy body in the solar system where eruption processes have been seen without doubt in action.

Recently active worlds: Ganymede (Jupiter's satellite), Dione, Tethys (Saturn's satellites), Ariel, Miranda and Titania (Uranus's satellites). These are worlds where there are evidences of both tectonic proceses on a global scale and vast volcanic outpourings which occurred after the end of late heavy bombardment.

Ganymede (diameter 5262 km, figure 4) represents the best known of these bodies. Ganymede is divided into dark heavily cratered terrains that occur as polygonal regions and poorly cratered bright terrains in the form of bands that separate the heavily cratered polygons. The bright terrains are usually strongly grooved and ridged and provide unequivocal evidence of widespread-to-global volcanism and tectonism. In some place, bright terrains are smooth, notably where they overlay the dark terrains. This suggest that the bright terrains were emplaced during extensional tectonic events, such as an extruded low-viscosity fluid, probably liquid water or a mush of water-ice crystals. The age of the end of this flooding is strongly dependent on cratering models in the outer solar system, and may be estimated to be 3–3.5 Gyr.



(a)



(b)

Figure 4. (*a*) Global view of the south pole of Ganymede. Flat terrains probably consist of large frozen water flows. Ridged and grooved terrains are deformed ice flows. Numerous impact craters indicate that this flooding stopped 3.5 Gyr ago (NASA–Voyager). (*b*) Detailed view of Ganymedean surface. Flat and ridged terrains are crosscut by an elongated caldera-like feature. Viscous flow (probably ice–liquid mush) is visible inside the caldera (NASA–Galileo).

Large-scale resurfacing and flooding without tectonics is visible on DIONE (diameter 1120 km) and on one area of TETHYS (diameter 1060 km), while evidence of water volcanism and resurfacing related to tectonism exists on other parts of Tethys, and on TITANIA (diameter 1580 km) and ARIEL (diameter 1158 km). On Ariel, canyons called 'Chasma' have clearly been flooded by some kind of volcanic flow processes which somewhere produced sinuous rilles with scales and morphology comparable with their lunar maria counterparts.

MIRANDA (diameter 472 km) is one of the most remarkable and complex worlds in the solar system despite its small diameter. Half of Miranda is a uniform densely cratered plain, while the other half is occupied by

regions of younger grooved terrains, the detailed appearance of which has never been found elsewhere in the solar system. These regions are called 'corona' and exhibit belts of parallel or crosscutting ridges. These ridges are commonly interpreted as fracture-controlled extrusions of warm ice or mush. The pattern of ridges is not understood at all. Somewhere, the ridges seem submerged by lava-flow-like structures.

Dead worlds: Callisto (Jupiter's satellite), Iapetus, Mimas, Rhea (Saturn's satellites), Oberon, Umbriel (Uranus's satellites). The Voyager and Galileo fly-bys revealed six satellites as intensely cratered worlds. If some kind of volcanic resurfacing processes had existed, they ceased before the end of late heavy bombardment. Possible volcanic morphologies have now almost completely disappeared, with the possible exception of Callisto and Rhea.

On CALLISTO (diameter 4800 km), some flat plains are associated with fractures surrounding a large impact (Valhalla) and may be due to some water resurfacing.

On RHEA (diameter 1530 km), one-third of the known surface is less cratered than the other two-thirds. Possible clues that there was endogenic activity on Rhea are given by features such as linear troughs and ridges, which may be interpreted as subdued volcanic vents.

Origins of volcanism on the icy satellites

Icy bodies are not large bodies (smaller than or equal in size to Mercury), and their volcanism should be completely extinct. Moreover, the size does not display a significant effect on internal activity: the small Enceladus is still active, while the large Callisto never has significant activity. Two physical reasons may produce abnormally active volcanism.

(1) With the exception of the unimaged Pluto, all the icy bodies are satellites of large planets, and permanent or transitional orbital resonances with other satellites may produce permanent or transitional orbital eccentricity and tidally generated heat. That would explain the difference between Ganymede and Callisto: Ganymede is closer to Jupiter than Callisto; tidal heating may have been greater for Ganymede and sufficient to produce volcanism during the first billion years. Tidal heating was never sufficient for Callisto. The heat sources of Enceladus and other bodies smaller than 1000 km in diameter are more uncertain and may be searched for in temporary orbital resonances with other satellites. The nature and shape of convective motions inside icy mantles are unknown at present.

(2) If a temperature of 1100 ºC is necessary to melt silicates, a temperature of about 0 ºC is sufficient to melt pure water ice, and a temperature of –100 ºC induces the melting of a water–ammoniac ice mixture. Even low internal heating could increase the temperature sufficiently to reach the melting temperature and to produce water or water–ammoniac volcanism.

The case of Triton is more complex. Volcanism-induced resurfacing which occurred everywhere is probably due to radiogenic and tidal heating, as for Ganymede or other large icy satellites. Such mechanisms could explain the active plumes. However, these active plumes are only located on the southern polar cap, and an exogenous origin is possible. The polar cap is made of transparent nitrogen ice covering a darker substrate. This was Tritonian 'springtime' when Voyager 2 imaged the south pole of Triton in 1989, and the temperature was increasing. Nitrogen ice is transparent and allows most of the sunlight to heat the underlying darker layer. A rise of only 10 ºC of this dark layer above the surface temperature of –236 ºC would cause the vaporization of the base of the nitrogen ice layer and its eruption as a nitrogen gas plume, through the icy superficial crust.

Voyager Mission

If one were to ask a space scientist which of all the space missions ever flown he or she would consider the most scientifically successful, there is a good chance that NASA's Voyager Mission to Jupiter, Saturn, Uranus and Neptune would be mentioned more than all others combined. Launched from Cape Canaveral, Florida, in 1977 (Voyager 2 on 20 August and Voyager 1 on 5 September), these two hardy spacefarers celebrated their 20th anniversary in late 1997. Although their last planetary encounter was in 1989, they continue to collect useful data about the outer solar system and will probably celebrate their 40th anniversary in the year 2017 before their useful lives come to an end.

As early as 1966, engineers at NASA's JET PROPULSION LABORATORY (JPL) realized that it was possible with a single spacecraft to visit all of the giant gaseous planets in the solar system (JUPITER, SATURN, URANUS and NEPTUNE). After rejecting a number of more costly and more ambitious missions proposed by JPL, NASA approved a two-spacecraft Mariner Jupiter/Saturn Mission to take partial advantage of this fortuitous planetary alignment. The initial approval was for a 4 yr mission, including flybys of Jupiter and Saturn only by each of the two Voyager spacecraft. The official project start date was 1 July 1972, and launch was slated for the late summer of 1977. The mission was renamed Voyager shortly after project start. (The name Voyager had previously been selected by JPL for an unsuccessfully proposed mission to Mars. The basic concepts of that earlier Voyager mission were essentially reproduced in the successful dual-orbiter, dual-lander VIKING MISSION to Mars.)

The two Voyager spacecraft were built with identical engineering designs and identical scientific payloads. Part of that design was based on results from the smaller PIONEERS 10 and 11. Neither Pioneer spacecraft detected dust particles in their passages through the Asteroid Belt. As a consequence, the Voyager dust detector was discarded in favor of a plasma wave detector. The eleven investigations and their Principal Investigators or Team Leaders are given in table 1. The two Pioneer spacecraft also experienced very high levels of radiation in the vicinity of Jupiter; this led to a campaign to build the Voyager engineering and scientific hardware to be resistant to damage from these higher radiation fields.

Although the Voyager Mission was approved by NASA for the 4 yr flight including Jupiter and Saturn encounters only, NASA gave approval for JPL to design the mission of Voyager 2 (but not the spacecraft or its scientific payload) to go beyond Saturn to Uranus and Neptune (or to Pluto). As noted earlier, Voyager 1 was launched more than two weeks after Voyager 2. However, the flight to Uranus required a slower flyby of Saturn; Voyager 2's flight to Jupiter and Saturn was therefore a few per cent slower than that of Voyager 1. It was prior knowledge of that fact that prompted the 'reverse numbering' of Voyagers 2 and 1. Voyager 1 encountered the planet Jupiter on 5 March, 1979. Voyager 2 followed on 9 July of that same year. Voyagers 1 and 2 flew by Saturn on 12 November 1980 and 25 August 1981, respectively.

Following Voyager 1's successful flyby of Saturn, which included a very close approach of Saturn's largest

moon, TITAN, NASA gave approval for the Voyager Project to target Voyager 2's Saturn encounter for a continuation on to Uranus. The transition between the primary mission and the Voyager Uranus/Interstellar Mission (VUIM) occurred on 1 October 1981. Similar approvals were given for subsequent portions of the extended Voyager Missions. The Voyager Neptune/Interstellar Mission (VNIM) started 1 April 1986; the Voyager Interstellar Mission (VIM) began 1 October 1989. Because of Voyager 1's close approach to Titan, the spacecraft's trajectory passed well south of Saturn. The massive gravity of Saturn pulled Voyager 1's path northward of the ecliptic and hence northward of the orbits of Uranus, Neptune and PLUTO. However, the measurements Voyager 1 makes of interplanetary charged particles and magnetic fields continue to be of great interest to solar system scientists. Voyager 2 encountered Uranus on 24 January 1986, and Neptune on 25 August 1989; like Voyager 1, its mission is now directed at interplanetary and interstellar measurements.

The intensive data collection periods surrounding each of the planetary encounters generally included about 3 months prior to closest approach and one month thereafter. The first approximately two months of the encounter period constituted an 'Observatory' phase. 'Far Encounter' spanned the period from the end of the Observatory phase to about 1 day before closest approach. 'Near Encounter' generally lasted about 2 days, more or less centered on the closest approach to the relevant planet. A 'Post Encounter' of about 1 month concluded each planetary encounter period. Each of these phases included two or three sequence computer 'loads', which updated the central computer and sequencer (CCS) contents. The CCS would then control spacecraft activity, including recording to and playback of the digital tape recorder storage device. A full tape recorder would hold the equivalent of about 100 full-resolution (i.e. uncompressed) images.

Because Voyager was designed to operate at great distances from the Sun where solar panels were ineffective, power was (and is) provided for each of the Voyager spacecraft by means of radioisotope thermoelectric generators (RTGs). These 'batteries' generate electricity by transforming heat radiated by the natural decay of plutonium dioxide. These batteries, which utilize non-fissionable plutonium-238, are highly reliable and long lived, a perfect combination for a mission like Voyager. The RTGs carried by each Voyager generated about 500 W of power at launch and are decreasing in output by about 5 W yr^{-1}. This will permit them to continue to power the two spacecraft with usable amounts of wattage until about the year 2020.

Communication with the spacecraft occurred via digitally modulated radio signals. Commands transmitted from the ground occurred at S-band, near a frequency of 2113 MHz. Data were transmitted to the ground at X-band, near a frequency of 8415 MHz. Early in its mission, the Voyager 2 primary radio receiver failed. Following a week of no command receipt by Voyager 2, a computer-stored failure algorithm automatically switched to the spacecraft's backup receiver. It was soon discovered that the backup receiver was 'tone deaf'. In other words, if the S-band signal arriving at the spacecraft differed by more than 96 Hz from the receiver's frequency, it would not be detected. Factors such as the velocity of the spacecraft and the rotation and revolution of the Earth would cause changes (due to Doppler shifting of the transmitted radio signal) that easily exceeded 96 Hz. While adjustments in the transmitted S-band frequency could be made for the factors mentioned, indeterminate shifts in the central receiver frequency would occur each time power usage (and hence temperature) would change by more than a couple of watts. Power changes were therefore minimized; when power usage changes were necessary, a command moratorium of from 24 to 72 h was honored, providing enough time to determine the new receiver frequency. Voyager engineers became very proficient at dealing with this shortcoming of Voyager 2, and it never substantially limited the spacecraft's capabilities.

Another Voyager 2 hardware problem occurred during the Saturn flyby. Voyagers 1 and 2 are three-axis stabilized spacecraft. Except for brief periods of time, the 3.7 m wide high-gain communications antenna is kept pointed at Earth, and the star tracker is locked on a selected bright star. The cameras and spectrometers were then pointed at their targets by means of a steerable two-degree-of-freedom scan platform. One of the two axes of that scan platform seized about half an hour after Voyager 2's closest approach to Saturn. The problem was traced to the migration of lubricant out of the gear train during periods of heavy usage. Motion was restored a few days later. Careful study of the characteristics of the failure, both from spacecraft engineering data and from life tests on similar gear trains at JPL, enabled engineers to devise a usage plan that would avoid another seizure. The scan platform operated flawlessly during the Uranus and Neptune encounters.

There are several examples of engineering 'tricks' that improved the Voyager science return. Normal limit cycle motion of the spacecraft was controlled within 0.05° in each of the three spacecraft axes. Attitude knowledge was provided by monitoring the Sun Sensor and Star Tracker. Attitude control was accomplished by 200 ms bursts of hydrazine fuel through appropriate thruster jets. Using that scheme, the motion of the camera field of view across the sky was slower than the motion of an hour hand on a clock. Nevertheless, long exposures and low light levels demanded even slower rates. The Attitude and Articulation Control System (AACS) aboard Voyager 2 was programmed to shorten the thruster pulses, slowing the resultant rates across the 0.05° deadband to less than 10% of the normal quiescent rate, almost eliminating image smear in more than 90% of the images obtained at Uranus and Neptune.

Another scheme to reduce image smear involved rotating the cameras at a rate that matched the apparent motion of a nearby satellite (moon) during flyby of that satellite. This scheme involved using onboard gyroscopes for attitude reference (instead of the Sun Sensor and Star Tracker). The AACS was fooled by doctored data in the spacecraft computer into thinking the gyroscopes were drifting. As the AACS compensated (as it was designed to do) for this false 'gyro drift', it caused the spacecraft to turn in a way that kept the cameras pointed at the nearby moon without having to use the (somewhat jerky) movement of the scan platform. This technique was first used to obtain unsmeared images of Saturn's moon Rhea and was particularly successful in image sequences of Uranus's moon MIRANDA, and Neptune's moon TRITON.

The scientific findings of the Voyager Mission have been the most notable of its contributions. The individual scientific articles based on Voyager data now number in the thousands, and Voyager data continue to be the source of detailed comparative studies of the giant planets and their rings, satellites and magnetospheres (the magnetic fields surrounding each of the giant planets and the electrically charged particle population trapped within or traversing those magnetic fields).

Atmospheres and interiors

Voyagers 1 and 2 obtained the first detailed composition, temperature and pressure profiles of the atmospheres of Saturn, Uranus and Neptune and improved our understanding of those characteristics of the atmosphere of Jupiter, previously visited by Pioneers 10 and 11. The GALILEO MISSION has dropped an instrumented probe into Jupiter's atmosphere and completed its orbital mission around the solar system's largest planet, improving on many of the measurements made by Voyagers 1 and 2. Ulysses also completed a high-latitude flyby of Jupiter on its way to study the polar regions of the Sun (see SOLAR WIND: ULYSSES). The CASSINI/HUYGENS MISSION is designed to make enormous improvements in our understanding of Saturn's atmosphere and interior as it circles the planet for 4 yr starting 1 July 2004. However, for Uranus and Neptune, the Voyager *in situ* results and the high-resolution and high-phase-angle remote-sensing observations will probably remain unique for the foreseeable future.

Our understanding of the interiors of the giant planets is based largely on theoretical considerations. However, there are many bits and pieces of information, mostly from Voyager results, that serve to constrain the range of viable models. Careful measurements of the paths of the Voyager spacecraft helped determine accurate measurements of the masses of the giant planets and of their entire systems. Voyager determined the rotation rates of the interiors of Saturn, Uranus and Neptune. (Jupiter's interior rotation rate was determined by radiowave measurements made from Earth.) The orientations of the strange magnetic fields of Uranus and Neptune (see below) offer additional clues. Excess heat in the form of infrared energy escaping from each of the four planets is also important in constraining models of the interior.

Rings

The Voyager spacecraft revealed the enormous amount of detail in the rings of Saturn, discovered the rings of Jupiter and provided the first detailed images of the rings of Uranus and Neptune. Ring data from Voyager have raised even more questions on the nature of ring systems than they have answered. The answers to those questions may be important to studies of the asteroid belt, the Oort cloud of comets, galactic structure and clusters of galaxies within the universe.

Satellites

Voyager imaged Earth's MOON. Three new satellites of Jupiter (Metis, Adrastea, and Thebe) were discovered in Voyager data, and Voyager images were obtained of eight of Jupiter's 16 known moons. Only the outer eight moons, all thought to be tiny captured asteroids, were missed. Voyager revealed active volcanoes on IO, an obviously fractured and geologically young icy surface on EUROPA (first evidence of a global subsurface ocean), a variegated array of surface structures on GANYMEDE and an ancient cratered icy surface on CALLISTO. The sizes, masses, densities and reflectivities of the four Galilean satellites were also measured, showing Ganymede to be the solar system's largest satellite, Europa to be the brightest Galilean satellite and a decrease in bulk density with increasing distance from the planet (presumably due to water depletion from the closer satellites due to heat from Jupiter).

At Saturn, four new satellites (Pan, Atlas, Prometheus and Pandora) were discovered in Voyager data. These data also showed that Janus and Epimetheus, previously thought to be a single satellite, were actually two satellites with remarkably similar orbits. Three satellites (Telesto, Calypso and Helene) were discovered from Earth as a result of the increased interest in Saturn generated by the approaching Voyager. Voyager revealed that Titan was the solar system's second largest satellite, and the only one with a substantial atmosphere. Titan is covered by a high atmospheric haze, which hides the surface from visible imaging. However, infrared and radiowave measurements penetrated to the surface of this strange moon, which may be the only body in the solar system (other than Earth) with both liquid and solid material at its surface. Voyager obtained images of all 18 known satellites of Saturn. These images revealed a geologically young surface on ENCELADUS, erratic rotation for HYPERION and a remarkably sharp boundary between dark material on Iapetus' leading face and bright material on its trailing face. Phoebe, apparently a captured asteroid, was revealed to have the darkest surface among Saturn's satellites.

Voyager added 10 new satellites (Cordelia, Ophelia, Bianca, Cressida, Desdemona, Juliet, Portia, Rosalind, Belinda and Puck) to the five previously known at Uranus. Miranda has unique surface features known as coronae owing to their strange concentric patterns. Six new satellites (Naiad, Thalassa, Despoina, Galatea, Larissa and Proteus) were added to Neptune's prior repertoire of two. Triton was discovered to have nitrogen ice, extremely cold temperatures (32 K), and geyser-like plumes spewing dust through cracks in the icy surface.

Magnetospheres

Little was known about the magnetospheres of the giant planets before the Voyager flybys. Pioneers 10 and 11, as Voyager 'pathfinders', had made preliminary measurements of Jupiter's magnetosphere, and Pioneer 11 probed Saturn's magnetosphere. Voyager made significant improvements in those measurements and provided the first measurements of the magnetospheres of Uranus and Neptune. The magnetic fields of the latter two planets were found to be highly inclined to the planetary rotation axes, something previously expected only for certain stars.

The final frontier for Voyager is a search for the outer edge of the heliosphere (the Sun's magnetosphere). Theoretical calculations show that the boundary should be at a distance of between 80 and 120 astronomical units (AU) (1 AU is the mean distance between Sun and Earth). Voyager 1 crossed 80 AU in 2001; Voyager 2 reaches that distance in 2006. Once Voyager 1 is beyond the heliosphere, humanity will be able for the first time to sample the magnetic fields and charged particles in the space between the stars.

The two Voyager spacecraft are still sending back data, 25 years after their launch. Voyager 1 is now the most distant human-made object; in August 2002 it was about 85 times as far from the Sun as the Earth and Voyager 2 was about 68 times the Sun–Earth distance. They are both continuing outwards at about 3 AU per year (slightly more for Voyager 1 and slightly less for Voyager 2). The Voyager team at JPL still receives information almost daily from the Voyagers which are examining the far reaches of the solar wind.

Bibliography

A detailed pre-launch description of the Voyager mission, the spacecraft and the scientific investigations is given in *Space Science Reviews* **21** pages 75–376 (1977).

Voyager scientific results have been chronicled in multiple dedicated issues of *Science*, *Nature*, *Icarus* and the *Journal of Geophysical Research*. They have also resulted in at least six separate many-hundred-page scientific texts on planetary science published by The University of Arizona Press.

Vulcan

The name given to a hypothetical planet believed by Urbain Le Verrier to exist within the orbit of Mercury. At the request of François Arago, Le Verrier first studied the orbit of Mercury in the early 1840s. He managed to explain the greater part of the discrepancy between its calculated and observed positions (the advance of its perihelion) as being caused by gravitational perturbations by the other planets. The residual discrepancy eluded him, and he abandoned the problem as intractable. He returned to it in 1859, having in the meantime successfully predicted the existence of Neptune. Now he invoked an intramercurial planet or asteroid belt as the cause of Mercury's irregularities. Shortly after, he heard that a physician and amateur astronomer, Edmond Lescarbault, had observed a small body in transit across the Sun's disk. Le Verrier examined Lescarbault's observations closely and, convinced they were genuine, announce the existence of a new planet which he named Vulcan. Subsequent sightings were reported but never confirmed. Vulcan is now known not to exist.

Vulpecula

(the Fox; abbrev. Vul, gen. Vulpeculae; area 268 sq. deg.) a northern constellation which lies between Cygnus and Sagitta–Delphinus, and culminates at midnight in late July. It was introduced as Vulpecula cum Ansere (the Fox and Goose) by the astronomer Johannes Hevelius (1611–87) of Danzig (Gdansk), who included it in his atlas *Firmamentum Sobiescianum sive Uranographia* of 1687.

A small, inconspicuous constellation, the brightest star in Vulpecula is α Vulpeculae, magnitude 4.4. The Milky Way passes through Vulpecula and the constellation contains a number of open star clusters and planetary nebulae, including Cr 399 (Brocchi's Cluster, the Coat-hanger), which consists of about a dozen stars of magnitudes 6–8, elongated east–west, NGC 6940, another open cluster with about 100 stars fainter than ninth magnitude, and M27 (NGC 6853), the Dumbbell Nebula, an eighth-magnitude planetary nebula.

W M Keck Observatory

The W M Keck Observatory, located on the island of Hawaii, operates the world's two largest optical/infrared telescopes, each with a primary mirror 10 m in diameter, near the 4200 m summit of Mauna Kea. Made possible through grants totaling more than $140 million from the W M Keck Foundation, the observatory is operated by the California Institute of Technology, the University of California and the National Aeronautics and Space Administration (NASA), which joined the partnership in October 1996. The Keck I telescope began science observations in May 1993; Keck II in October 1996.

A staff of 80 scientists, engineers, technicians and support personnel operate the observatory whose administrative facility is located in Waimea, Hawaii, and whose mission is to provide a world-class research facility for astronomers from Caltech, University of California, NASA and the University of Hawaii. Over 400 astronomers per year are involved with observations from the Keck telescopes, which are carried out from Waimea via a fiber-optic link to the summit of Mauna Kea.

The Keck telescopes employ a unique segmented design for their primary mirrors: 36 1.8 m diameter hexagonal segments are fitted together like a floor-tile mosaic to form each primary, the segments being aligned with respect to each to a tolerance of one-millionth of an inch under computer control. This expandable technology is that most likely to be adopted for the giant telescopes being planned for the 21st century.

A $55 million project funded by NASA is aimed at joining the two Kecks, along with four 1.8 m 'outrigger' telescopes, as an infrared interferometric array to achieve unprecedented angular resolution, by the year 2003.

The first test observation obtained by linking the two Keck 10 m telescopes was made on 12 March 2001. Light from HD61294, a faint star in the constellation Lynx, was captured by both Keck telescopes. The collected light waves were combined and processed with a beam combiner and camera. To phase the two telescopes properly, adaptive optics on both telescopes removed the distortion caused by the Earth's atmosphere. In addition, the optical system in the tunnel adjusted the light path to within a millionth of an inch.

Major discoveries from this young observatory include: the discovery of several planetary systems around other stars; the identification of gamma-ray bursters as being at cosmological distances; the discovery of the most distant objects in the universe; the measurement via supernova observations of the apparent acceleration of the universe.

Warner & Swasey Observatory

Located at Washburn University in Topeka, Kansas, home of the Warner & Swasey 29 cm refractor. Built in the late 1800s, the telescope was displayed at the 1912 World's Fair, then acquired by Washburn College. Crane Observatory was built on campus to house the telescope. The Warner & Swasey survived a tornado in the 1960s. During telescope refurbishment, which was completed in 1998, all of the original parts were retained.

Water Cycle

The Earth's water cycle is the endless circulation of water on a planetary scale, from ocean to continent through the atmosphere and back to the ocean, under the driving influence of solar energy and gravity. This main cycle in fact consists of many overlapping loops and branches at all scales, involving more or less durable storage, more or less rapid transfers, more or less intense transformations between water phases. Because of this complexity, it was only in the late 16th and 17th centuries that the concepts of water cycle and balance arose, with the pioneering work of B Palissy, P Perrault, E Mariotte and E Halley founding scientific hydrology. Earth is a system approximately closed for water but largely open for energy. The particular properties of water together with the strong coupling between water and energy cycles regulate the Earth's mean temperature and shape weather and climate patterns and their fluctuations (see CLIMATE). The water cycle interacts also strongly with most biogeochemical cycles, with long-term environmental feedbacks. Human activities have an increasing impact on the water cycle and the coupled fluxes, with some alarming consequences for the quantity and quality of water resources.

Properties of water

Water (H_2O) is a very stable molecule (covalent link), which has very specific physicochemical properties, mostly because of its dipolar structure and the related hydrogen link between molecules. These properties explain its multiform importance within the Earth's hydrosphere and its four main functions as resource, agent, vector and biotope.

- Its three phases (solid, liquid, vapor) are present within a relatively small range of temperature, corresponding to the temperature range observed on the Earth.
- Its very high latent heats of vaporization (2.454 MJ kg^{-1} at 20 °C) and fusion (0.334 MJ kg^{-1}) play a major role in the heat transfer by water through the atmosphere.
- Its high specific heat and low thermal conductivity make water bodies very good thermal regulators and water fluxes very good heat convectors: oceans play a major role in heat storage and transfer.
- Water vapor absorbs most of the infrared and ultraviolet radiation but is transparent to visible radiation; atmospheric vapor leads to the 'greenhouse effect', while liquid water and solid water have contrasting reflectivities. These radiative properties are central to the thermal budget of the Earth (see GREENHOUSE EFFECT).
- Because of its high dielectric constant, water is an excellent solvent, able to alter most minerals: natural waters are in fact more or less dilute aqueous solutions, providing nutrients to aquatic life and contributing by their movement to the redistribution of substances; water can also combine with many substances.
- Its density is maximal at 4 °C, permitting ice to float over liquid water: freezing and warming of water bodies occur from the top, progressive freezing of the whole ocean being avoided.
- Its low viscosity makes it a very mobile liquid, able to occupy all the space available, even within very small pores, and its surface tension allows soil water retention by capillarity against gravity, by which vegetation can persist between two rainfalls.
- Water molecules present several isotopic combinations, whose relative abundances provide very useful (paleo)thermometers and tracers of the water's origins.

Origin and uniqueness of water on the Earth

Earth, the 'blue planet', is unique within the solar system by the presence in great abundance of water in its three phases.

The Jovian planets (Jupiter, Saturn, Uranus, Neptune) are composed of light elements, including hydrogen and helium, and most of their satellites contain a large fraction of water ice, because of the very cold conditions prevailing so far from the Sun. The Jovian satellite Europa, in addition, might contain a water ocean below its icy crust. In the Telluric planets (Mercury, Venus, Earth, Mars) constituted of heavy elements, water was partly outgassed by tectonic and volcanic activity and partly brought by impacts of meteorites of asteroidal or cometary origin. The fate of water in the Telluric planets has differed largely according to the very different temperature and pressure conditions prevailing on each planet, mostly as a result of their distances from the Sun (figure 1).

While Mercury no longer has an atmosphere and probably still contains only a little ice in cold regions, on Venus the thick carbon dioxide atmosphere is much too hot for water condensation because of a strong greenhouse effect, and most outgassed water vapor was subsequently photodissociated (photolysis) (see VENUS). Mars is currently cold and dry because of its thin carbon dioxide atmosphere, but there is much geomorphological evidence of past water-related erosion, and some limited water is probably still contained in permafrost and ice caps (see MARS). Earth is the only planet where the three water phases coexist: a greenhouse effect due to the presence of water vapor and carbon dioxide in its atmosphere has maintained temperature conditions permitting the condensation of very huge amounts of outgassed water, and therefore the development of life. Uniformly distributed over the whole planet's surface, the depth of all the water on Earth would amount to about 3000 m, as compared with rough estimates of about 200 m for Mars and 0.20 m for Venus.

Main reservoirs and fluxes

The total amount of water within the Earth's hydrosphere (that is, above and within the upper 2 km of the crust) can be considered as constant, even though there are very small net water exchanges with both space (loss by

diffusion, gain by icy comets) and the Earth's mantle (loss by subduction, gain by volcanic activity), where there is a much slower tectonic water cycle. This huge amount of water (about 1386 million km^3, of which only 2.5% is fresh water) is stored in several main interconnected reservoirs differing by the volume and quality (salt, fresh) of the water they contain. The fluxes they permanently exchange within the water cycle control their renewal rates, which differ largely according to their size and the water phase they store. Current estimates of global storages and mean annual fluxes are still affected by rather large uncertainties especially for groundwater (compare for instance values in table 1, table 2 and figure 2).

The largest reservoir is by far the world ocean, which covers 71% of the 510 million km^2 of Earth's surface with a mean depth of 3700 m. It contains 96.5% of all the water, as salt water, and has a long mean residence time of 2500 yr.

Continents store the remaining 3.5% of water in several main reservoirs with a very large range of sizes and renewal rates.

- Ice caps, glaciers and permanent snow cover store 1.74% of total water over 3% of Earth's surface (essentially in the Antarctic). This solid phase represents 69% of all fresh water, with a very long residence time in ice caps (10^4 yr).
- Groundwaters within the upper 2 km of the Earth's crust contain about 1.7% of total water (45% only as fresh water), with very variable residence time (1–10^3 yr) according to their depth and the porous media properties. Soil moisture accounts for 0.001% only.
- Surface water (lakes, rivers, swamps) represents only 0.01% of all water, most as fresh water. The mean residence time is short for rivers (about 18 days) and much longer for lakes (up to 1000 yr).
- Biomass contains only 0.0001% of total water, but the high water content (>70%) of most plants and living organisms is renewed within a few hours or days.

The atmosphere stores 0.001% of total water, mostly as vapor. Liquid and solid phases are also present in clouds, which cover more than 60% of Earth's surface on average. Atmospheric water corresponds to an equivalent height of only 26 mm but is frequently and rapidly renewed in 9 days, ensuring an intense recycling of water.

The global water cycle presents two main interconnected loops of different intensity (figure 2).

- Ocean and atmosphere exchange large fluxes: the ocean loses much water by evaporation (434 000 km^3 yr^{-1}; 1202 mm yr^{-1}), a flux only limited by the energy available. Most of this flux returns directly to the ocean by precipitation (398 000 km^3 yr^{-1}; 1102 mm yr^{-1}).
- Continent and atmosphere exchange fluxes that are smaller because less water is available: precipitation on continents (107 000 km^3 yr^{-1}; 719 mm yr^{-1}) is in great part compensated by evapotranspiration (71 000 km^3 yr^{-1}; 477 mm yr^{-1})—that is, water evaporated from the land surface and transpirated by vegetation.
- The water balances of both loops are equilibrated by the fluxes they exchange: vapor flux in excess from the ocean (36 000 km^3 yr^{-1}; 100 mm yr^{-1}) is transported by atmospheric circulation over continents, while an equivalent flux of precipitation excess on the continent (36 000 km^3 yr^{-1}; 242 mm yr^{-1}) returns to the ocean by gravity as surface and subsurface runoff.

Endorheic/exorheic areas: not connected/connected to the ocean.

Globally precipitation and evaporation fluxes are equal and amount to 505 000 km^3 yr^{-1} (990 mm yr^{-1}).

Space and time variations

Mean global values of storage and annual fluxes in fact mask very large variations at different scales in both time and space. Variations in evaporation (E), precipitation (P) and the resulting continental runoff are mainly due to seasonal and latitudinal variations in solar energy modulated by seasonal thermal contrasts between ocean and continent (figures 3 and 4). An observation network and remote sensing mainly from satellites help to assess and monitor the variability of water storages and fluxes and the environmental factors controlling them (see SPACE-BASED OBSERVATIONS OF THE EARTH).

In the intertropical zone, where solar energy is maximal, the redistribution of water and energy within the atmosphere is ensured by the rather stable vertical circulation within the Hadley cells generated by large vertical contrasts in temperature, in the absence of a strong Coriolis effect. In the equatorial zone, the convergence of trade wind systems generates the uplift (low pressure) of warm air moistened by high evaporation from the ocean: this results in heavy convective precipitation exceeding the local evaporation, which is reduced by frequent cloud cover ($P > 2000$ mm yr^{-1}, $E < 1600$ mm yr^{-1}). Inversely,

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

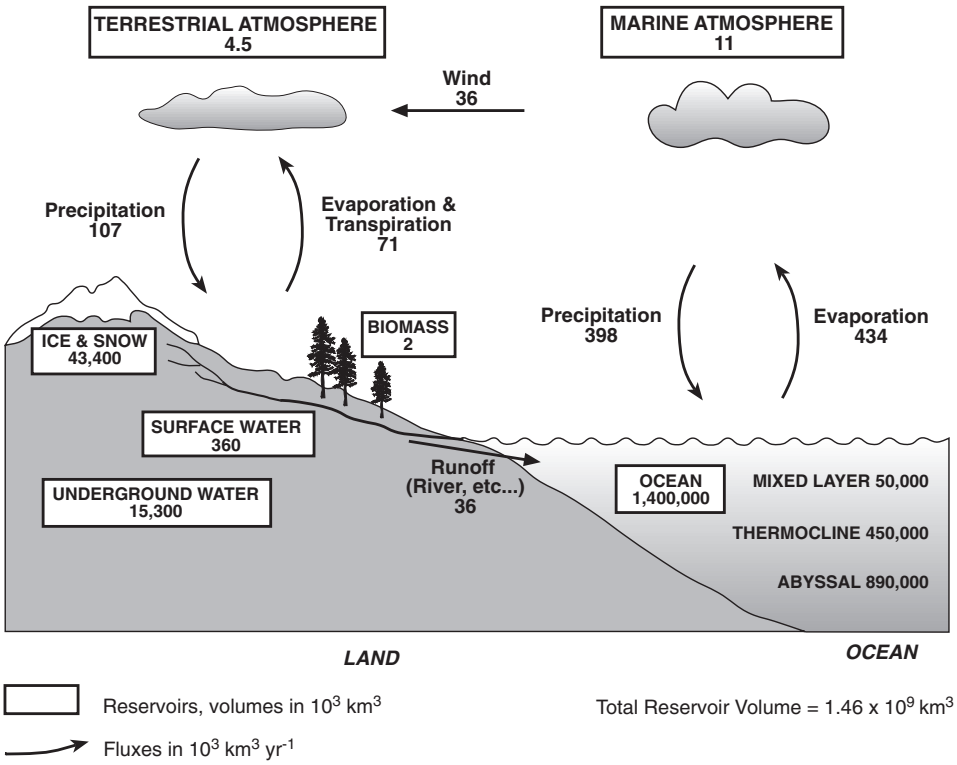

Figure 2. The water cycle at a global scale. Adapted from National Research Council (1991). Reproduced by permission of National Academy of Sciences.

subsidence of warm and dry air (high pressure) in the subtropical zones favors evaporation, which exceeds local precipitation ($P < 1200$ mm yr^{-1}, $E > 1800$ mm yr^{-1}).

In the mid-latitude zones (between 30° and 60°), the redistribution of water and energy from tropics to poles is rather organized horizontally, through successions of unstable eddies moving from west to east and generated by horizontal contrasts in temperature and by the Coriolis effect: cyclonic depressions provide precipitation, while dry anticyclonic conditions favor evaporation. At high latitudes, because of minimal solar energy and subsidence of cold and dry air (high pressure) precipitation and evaporation are very low (only a few mm yr^{-1} at the poles). In the extratropical zones, precipitation generally exceeds evaporation, but, while evaporation decreases rather regularly toward the poles, precipitation presents in the mid-latitude zone a maximum ($P > 1200$ mm yr^{-1}) associated with the depression systems.

This latitudinal climate zonation is most clearly observed on the ocean, where evaporation is only limited by the energy available. Differences in water ($P - E$) and energy balances associated with each climatic zone also generate a salinity pattern at the ocean surface (increasing by sea-water evaporation and freezing, decreasing by precipitation and sea-ice melting). Redistribution of water, heat and solutes within the world ocean is ensured by large-scale circulations and eddies (see OCEANS). While rapid surface currents are mainly induced by the prevailing surface winds, slow deep currents are mainly due to differences in water density (depending on water temperature and salinity). This thermohaline circulation generates the oceanic 'heat conveyor belt': in its main branch, cold dense water sinks in the Norwegian Sea, flows as deep water through the Atlantic ocean to the Indian and Pacific oceans where it warms and wells up and returns to the North Atlantic as dilute surface water in about 1000 yr.

On continents, where evapotranspiration is limited by water rather than energy, the climate pattern exhibits still more contrast, with warm deserts belts ($P < 300$ mm yr^{-1}) in the dry subtropical zones. This pattern is disturbed by other factors depending on the position, size and shape of each continent, whose cumulative effects result in a very large range of mean continental precipitation (from almost 0 to 12 000 mm yr^{-1}).

- Ocean–continent interactions: in the tropical zone, the western coasts of continents receive less precipitation than the eastern coasts, which are supplied by easterly trade winds carrying much moisture evaporated from the tropical ocean—for instance in the Amazonian basin.
- Continentality effect, especially in the middle latitude zones: precipitation on continents decreases from west to east, because of a progressive drying of air mass. Precipitation is more than 600 mm yr^{-1} in temperate

Western Europe, less than 100 mm yr^{-1} in continental Kazakhstan.

- Orographic effect: mountain ranges on continents, islands in oceans, act as barriers to dominant humid air mass. The windward side receives much more orographic precipitation than the leeward side—as is the case for the Western Cordillera in North America or the Hawaiian Islands.

These mean annual spatial patterns are modulated by diurnal and seasonal variations in insolation or longer-term fluctuations.

- At high altitudes as at high latitudes, a great part of winter precipitation falls as snow, forming a seasonal or even permanent snow cover affecting both water and energy cycles.
- Slight seasonal fluctuations of the Hadley cells around the equator explain the alternation of rain and dry seasons in the tropical zone.
- Seasonal variations in thermal contrasts between ocean and continent also explain the monsoon, providing huge amounts of summer precipitation to the Indian subcontinent.
- Multiannual fluctuations can also occur in the ocean–atmosphere system—as for instance the 'El Niño Southern Oscillation' (ENSO) affecting the Pacific but having dramatic effects on the water balance of the whole tropical zone.

In the much longer term (10–10^4 yr), cyclic variations in solar activity and Earth's orbital variations modify the insolation and the seasonal contrasts between both hemispheres, and therefore the climate and water cycle patterns. Ice caps and oceanic sediments provide paleoclimatic archives allowing us to date such fluctuations and characterize their hydrological impact, especially during the past glaciation–deglaciation cycles.

Precipitation generally exceeds evaporation on continents, but both are lower than on oceans at the same latitude, because less energy (higher albedo) and water (unsaturated soils) are available on continents. Water in excess within continental basins is collected by aquifer and river networks and returns in great part to the ocean as river runoff, with inputs spatially concentrated at the river mouths. The relative contribution to total river runoff to oceans is 16% for the Amazon alone, 27% for the five major river systems (draining 10% of continental areas) and 50% for the 50 major rivers, while 40% of river runoff is concentrated in the equatorial region (flowing mainly into the Atlantic). Endorheic basins, that are not connected to the ocean, represent 22% of continental areas (mainly in dry regions): runoff disappears by infiltration or accumulates in closed lakes and seas, where water evaporates—as in Lake Chad or the Aral Sea.

River runoff varies during the year with usually a strong seasonality of high and low flows, and successions of relatively short floods separated by longer recession periods—with the extreme case of ephemeral streams. Runoff variations are controlled by the time and space variabilities of precipitation and evaporation, which are very different. Precipitations are usually episodic and intermittent, more or less concentrated during rainy seasons and irregularly distributed in space, while the energy available for evapotranspiration is much more regularly and continuously distributed but more affected by diurnal and seasonal cycles. Evaporation intensity, which is limited by the insolation, varies within a much smaller range (0–10 mm day^{-1}) than precipitation intensity, whose maximal recorded local values are greater than 40 mm in 1 min, 400 mm in 1 h, 1900 mm in 1 day, 26 000 mm in 1 yr. Precipitation is often buffered seasonally in snow cover and glacier at high latitudes or altitudes, while evapotranspiration depletes soil moisture and is often reduced by summer water stress. The interannual variability is much larger for precipitation than for evapotranspiration. There is a large variety of river runoff regimes as a result of combinations of precipitation and evaporation regimes on their basins.

Water cycle on the basin scale

As the oceanic and atmospheric branches of the water cycle are presented elsewhere (see OCEANS and EARTH'S ATMOSPHERE), only its continental branch is detailed here, especially on the basin scale. A basin (or catchment) is defined as the total drainage area of a river at some specified outlet. Catchments, which can be defined at any scale and in any environment, are functional units very useful for both the study and the management of water resources.

The water balance of a catchment expresses the principle of water conservation: the incident precipitation is redistributed between runoff, evapotranspiration and water storage within the catchment, through a competition between three main sources of energy and driving forces: (1) gravity, which controls most flows of liquid and solid water and depends mainly on topography and morphometry; (2) the evaporative demand of the atmosphere, which controls vapor fluxes and depends on energy input (radiative, advective) and climatic conditions; (3) capillarity, which controls soil water retention and depends on the pore size distribution. At any point and any time, the dominant form of energy and thus the dominant component in the water balance depend on soil moisture conditions.

There is a large variety of surface and subsurface processes and pathways governing the hydrological response of a catchment to water and energy inputs from the atmosphere. They result in a strong vertical and lateral redistribution and recycling of precipitated water within a catchment. The main fluxes (evapotranspiration, groundwater recharge, streamflow) are usually generated simultaneously or successively by several processes, whose combinations are very variable in time and space. They are indeed controlled by local characteristics and

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

variations of atmospheric inputs, by the water storage and transfer properties of the various compartments and their geometry. Because of many functional thresholds, catchment response is usually highly non-linear, much depending on initial water conditions.

After some interception by vegetation, precipitation reaches the soil surface: snow remains stored on the surface until it melts, while rain infiltrates into the soil and recharges its water storage. When soil moisture exceeds some threshold depending on both soil texture and structure, water percolates further vertically to recharge groundwater. Biological activity, soil cracks and bedrock fissures, chemical dissolution (karstic cave systems,) often create networks of non-capillary macropores, which provide preferential pathways for free water, bypassing the less permeable bedrock or soil matrix. If the percolating flux exceeds the hydraulic conductivity of some subsurface layer, water in excess forms a perched groundwater or flows laterally as hypodermic interflow. Groundwater flows are essentially lateral and controlled by the conductivity of the porous media and the slope of the piezometric surface (which is the water table slope for unconfined aquifers). If the water table is shallow, precipitation can create locally rapid groundwater ridging by saturating its capillary fringe.

If precipitation intensity exceeds the infiltrability (depending on surface conditions), the soil surface is saturated from above: water in excess accumulates in small depressions, then flows as diffuse surface runoff. If subsurface lateral flows exceed locally a threshold depending on soil slope, depth and conductivity, soil surface is saturated from below: the excess flux exfiltrates as return surface flow. Precipitation on already saturated areas also tends to flow as surface runoff. Whatever its generating process (infiltration–excess, exfiltration, saturation–excess), surface runoff tends to concentrate in small rills to reach the stream channel but can also infiltrate downslope, depending on local surface topography, roughness and infiltrability.

Surface and subsurface processes contribute to streamflow, provided that the generated fluxes are connected to a stream channel. While the slow drainage of groundwater and soil water supplies stream baseflow between successive rainy events, floods are generated by rapid surface and subsurface flows and by direct precipitation on the river. Streamflow is routed downward as a turbulent flux controlled by the bed slope and roughness. Within the channel network, it increases at each confluence, decreases at each diffluence and accumulates in lakes and artificial reservoirs. Along the channel, streamwater and groundwater exchange fluxes whose direction and intensity depend on their water levels and the bed's conductivity. Flooding occurs when streamflow exceeds some threshold fixed by the bed geometry.

Both surface and shallow subsurface waters are subject to evapotranspiration, returning water vapor to the atmosphere. Evaporation combines a phase change (liquid or solid water to vapor), which consumes much energy (radiative or thermal), and a turbulent vapor transfer within the air, which increases with air saturation deficit and wind speed. Transpiration of the vegetation is the vaporization within leaf stomata of the sap flow extracted from soil by roots. Evapotranspiration is limited by the water and energy availability: evaporation of free water (wet vegetation, surface water, groundwater) depends on the available energy only, while capillary retention makes water in unsaturated soil less and less available when soil dries out. During dry periods transpiration, which exploits water within the whole root zone, lasts much longer than evaporation, which affects the soil top layer only. Stomatal regulation limits transpiration in dry soil conditions, to avoid vegetation wilting.

Any catchment presents a functional, spatial and temporal organization, because of the non-uniform and non-random distributions of the hydrological processes, factors and inputs: (1) at each point, process activation or deactivation results from a balance between water supply from above and local water storage or transfer capacities; (2) spatio-temporal variations of factors lead to some recurrence of conditions favorable or unfavorable to each process in some areas of variable extent and some periods of variable duration; (3) these variable active areas and periods are also contributing areas to main outfluxes only if they are hydraulically connected to the catchment boundaries. Because of many possible interactions and processes, zones of interface between atmosphere, vegetation and soil, or between surface water and groundwater are very sensitive to any change.

Coupled water, energy and matter cycles

Water and energy cycles are intimately coupled in the atmospheric and oceanic general circulations, controlling the radiation and energy balances at both global and local scales, and carrying energy from equator to poles and water from ocean to continent.

- Atmospheric water vapor maintains a rather high temperature at Earth's surface by a 'greenhouse effect', while the net solar radiation on surfaces is reduced by an 'albedo effect' depending on water phase and content and generating local thermal contrasts: reflection is very high for low clouds and ice or snow cover, low for water bodies and higher for dry bare soils than for moist vegetated soils.
- At evaporation sites, cooling occurs by vaporization consuming much energy (solar radiation, sensible heat), which is stored as latent heat in the water vapor; both are transported within the atmosphere by vertical convection and lateral advection to the precipitation sites where warming occurs by condensation releasing the latent heat as sensible heat in the atmosphere.
- Huge amounts of energy are stored as sensible heat in ocean water and transported from warm to cold regions by ocean currents (for instance the great 'heat conveyor

belt'): the ocean acts as a thermal regulator, tempering also seasonal climatic contrasts in many continental regions.

Water and matter cycles are also strongly coupled. On continents, water is a powerful agent of transformation and vector of material, depending on climate, topography, bedrock and soil types and vegetation cover. Water in porous media (rocks, soils) increases their weathering by low-temperature biogeochemical alteration and mechanical fragmentation and reduces their mechanical resistance. Surface flows of water, snow and ice generate soil and river bed erosion and carry downward the eroded material, while subsurface flows transport solutes washed out of the soil matrix and favor mass movements on slopes (landslides, solifluxion). At river outlets, the ocean receives large amounts of fresh water and its solute and particulate load, which modify locally its salinity and induce mixing processes. These point inputs of matter from continents contribute to compensate for the chemical precipitation and mechanical sedimentation occurring in the ocean and to maintain constant its mean salinity. Transport of material by water is still much more discontinuous and irregular than water flow, with many possible cycles of erosion–sedimentation, dissolution–precipitation, concentration–dilution. Evaporation and freezing tend to concentrate water solutions, while precipitation and melting tend to dilute them, even though precipitated water can reach high concentrations in some elements through the washing out of the atmosphere. As a result, water quality varies all along the different branches of the water cycle. In the long term, water activity modifies the landscape, with some possible feedback on water pathways and flows.

Since life originated in the ocean about 3.4 billion years ago, water is essential in the biosphere also, where its cycle is strongly coupled with other biogeochemical cycles. Water is the main component of biomass and is involved in major metabolic reactions such as photosynthesis and respiration. In terrestrial ecosystems, the redistribution within plants of nutrients extracted by roots is ensured by the sap flow induced by transpiration, and the development of vegetation modifies the surface water and energy properties. Vegetation maps reflect well at all scales the patterns of climate and water balance—as can be clearly seen in Africa, with the latitudinal succession of equatorial rain forest, tropical savanna, semi-arid steppe and subtropical desert. In aquatic ecosystems, which have some ability for self-purification, fresh, brackish or salt water bodies are biotopes for many living organisms linked in complex trophic chains, structured according to the vertical and horizontal patterns of water's physicochemical parameters. Continental wetlands, estuaries and coastal regions are aquatic interface ecosystems very sensitive to any change in water quality and supply.

Humans and water

Water is an essential part of humanity's environment: it is one of the most important natural resources for human life and activities; it is also a risk factor because of human vulnerability to water-related hazards such as floods and droughts, avalanches and landslides, waterborne diseases and toxicities. Humankind has therefore always attempted to regulate the availability of water resources and to protect itself against such risks. Human activities have also many other major impacts on the water cycle and the coupled fluxes, directly by modifying continental surfaces and altering water quality and indirectly through the climate changes they could provoke. While the water resources available tend to decrease, there is a rapid increase in water demand by several uses competing for limited resources. The struggle for water is becoming a major source of regional conflicts, which could be avoided only by a strong international collaboration in order to increase the necessary solidarities between upstream and downstream regions.

Very fast population growth and economic development have dramatically increased in recent decades the demand for high-quality fresh water, which is at present estimated to be about 3750 $km^3\ yr^{-1}$: about 2/3 for irrigated agriculture (providing 50% of food production), 1/4 for industrial production and 1/10 for domestic use. Because of their easy accessibility, rivers, lakes and superficial aquifers are the main sources of renewable fresh water resources. Evaluated by the difference between continental precipitation and evapotranspiration rates, current mean global estimations of renewable fresh water resources vary between 36 000 and 45 000 $km^3\ yr^{-1}$, about 95% as river runoff and 5% as groundwater. This global amount is much larger than the present demand, and should also largely meet the expected increase of about 10% each 10 yr. Technological development should help reducing water demand.

Unfortunately, these resources are very unevenly distributed throughout the year and present large variations from year to year, as shown by the intense Sahelian drought during the 1970s. They are also very unevenly distributed over continents, with patterns that do not match the spatial distribution of population and economic activities. Significant fresh water deficit already occurs in many regions, affecting their social and economic development: 35% of the world's population has very low or catastrophically low water supplies (for instance in North Africa) and 75% lives in regions where water use exceeds 20% of available renewable water resources, leading to a mining-type exploitation of deeper groundwaters, which rapidly become depleted because of their much lower renewal rates. Disparity in water resources, population growth and economic development already generates a very large inequality in fresh water availability per person: more than 500 l day^{-1} in developed countries, less than 50 l day^{-1} in some arid regions. Water supply is already one of the key issues for humankind.

Human activity also has a rapidly increasing impact on the natural behavior of most hydrosystems. River and aquifer regimes are often severely modified by water intake for irrigation, artificial reservoirs regulating discharge, or massive water exchanges between basins. Large-scale changes in land use (reafforestation–deforestation, urbanization, wetland drainage, field management) have deeply affected the precipitation redistribution between evapotranspiration, surface runoff and groundwater recharge. Irrigation with poor-quality water has generated soil salinization in many arid regions. The discharge in river courses of untreated domestic and industrial wastewater as well as groundwater recharge by polluted irrigation-excess waters have also drastically depleted water quality, further reducing the availability of good-quality fresh water. In the longer term, the possible global warming due to the anthropogenic increase in atmospheric carbon dioxide is likely to alter precipitation volume and seasonality, especially in arid regions, and to raise the sea level because of ocean thermal dilatation and ice cap melting: this would submerge many coastal lowland regions, which are among the most densely populated.

Conclusions

The water cycle is very complex at all scales, because of the numerous physical, chemical and biological processes involved and the high spatial and temporal heterogeneities of the controlling factors. Despite much progress recently achieved thanks to large interdisciplinary scientific collaborations and international effort to develop measurement and observation networks, there is still much to be done to understand and model all feedbacks and interactions with coupled energy and matter cycles. Impacts of increasing anthropic change and possible climate change on water cycle and resources are therefore still difficult to analyze and predict with some confidence. Nevertheless, the growing awareness of the numerous interactions controlling the water cycle and the scarcity and fragility of fresh water resources should contribute to improve the protection and management of both surface and subsurface water resources and the control of long-term effects of human activities on the Earth's water cycle. It is crucial for the future of both humankind and the 'blue planet'.

Wave–Particle Duality

The concept that electromagnetic radiation and subatomic particles behave in some respects like waves and in others like particles.

Various phenomena, such as interference and diffraction, clearly demonstrate the wave-like nature of light (and other forms of electromagnetic radiation). For example, if light of some particular wavelength, originating from a single source, passes through two adjacent narrow slits, each slit then acts as a source of light. Where the light waves spreading out from each slit meet, they interfere with each other, their amplitudes ('heights') adding together where they are in phase (e.g. where two wavecrests coincide) and canceling where they are completely out of phase (e.g. where a crest meets a trough). On the other hand, the particle behavior of light is demonstrated by the photoelectric effect, a phenomenon whereby certain substances emit electrons when illuminated by a beam of light, but do so only if the wavelength of the light is shorter than a particular minimum value. This behavior is consistent with light being a stream of particles (called photons) each of which carries a discrete quantity of energy that is inversely proportional to the wavelength of that light. If the energy of a photon exceeds the minimum energy that is needed to expel an electron, an electron will be ejected, but if the photon energy is less than this minimum, no electrons will be ejected.

Streams of subatomic particles exhibit wave-like behavior through phenomena such as interference and diffraction. For example, if a beam of electrons passes through two narrow slits before falling on a phosphor screen, which registers the arrival of each electron as a spot of light, the distribution of light spots takes the form of an interference pattern consistent with the pattern that would be produced by waves of a certain particular wavelength.

As Prince Louis Victor de Broglie (1892–1987) proposed in 1924, the wavelength (λ) associated with a particle of momentum, p, is given by $\lambda = h/p$, where h is the Planck constant (=6.63×10^{-34} J s). Since $p = mv$ (momentum = the mass of a particle multiplied by its velocity), $\lambda = h/mv$. The wavelength associated with a particle is known as the de Broglie wavelength. For example, the de Broglie wavelength for an electron of mass 9.11×10^{-31} kg traveling at a speed of 3×10^6 m s^{-1} (1 percent of the speed of light) is: $6.63 \times 10^{-34}/(9.11 \times 10^{-31} \times 3 \times 10^6) \approx 2.4 \times 10^{-10}$ m = 0.24 nm. For light of wavelength λ, the energy, E, of the photon is given by $E = hc/\lambda$, where c denotes the speed of light, and the momentum associated with a photon is $E/c = h/\lambda$

Wavelength

The distance between two successive crests of a wave motion. Usually, in transverse waves (waves with points oscillating at right angles to the direction of their advance), wavelength is measured from crest to crest. In longitudinal waves (waves with points vibrating in the same direction as their advance), it is measured from compression to compression. The term is applied to electromagnetic radiation which is regarded as a wave motion. For example, blue light has a wavelength of about 440 nanometers and red light about 700 nanometers. X-rays have wavelengths of the order of 10^{-10} meters and radio waves of the order of meters. Wavelength is usually denoted by the Greek letter lambda (λ); it is equal to the speed (v) of a wave train in a medium divided by its frequency (f): $\lambda = v/f$.

Wegener, Alfred Lothar (1880–1930)

German climatologist and geophysicist who suggested the phenomena of continental drift and plate tectonics. His idea was that a super-continent he called Pangaea had broken up, the pieces drifting to their present positions. His evidence was the fit of South America and Africa, and similarities in climate, fossil record and geology across the join. His path had been prepared by ALEXANDER VON HUMBOLDT and Frank Taylor, but his book, published in English in 1924, was scorned. His ideas are now widely accepted.

Weight

The force experienced by a body resting on, for example, the surface of a planet. A person standing on the Earth's surface experiences weight because the surface on which he is standing resists the effect of the force of gravity which otherwise would accelerate that person towards the center of the Earth. In other words, there is a reaction up through his feet equal and opposite to the gravitational attraction exerted upon him on Earth. The weight of a body depends upon the gravitational force to which it is subjected. On the surface of a planet it is equal to the mass of the body times the surface gravity. For example, a body that weighed 100 kg on the surface of the Earth would have the following weights on the surfaces of the bodies listed below:

the Moon	16 kg
Mars	38 kg
Jupiter	264 kg
the Sun	2790 kg
a white dwarf	30 000 000 kg

Werner, Johann (1468–1522)

Astronomer, mathematician, instrument-maker and geographer, born in Nuremberg, Germany, follower of Regiomontanus. Regiomontanus had suggested that the timing of eclipses and the orbits of comets could be used as clocks to determine longitude. Werner developed a practical version of this idea with the method of lunar distances (i.e. measuring the angle of the Moon from the Sun). He published this concept in *In Hoc Opere Haec Cotinentur Moua Translatio Primi Libri Geographicae Cl'Ptolomaei* (1514) and described an instrument with an angular scale on a staff from which degrees could be read off, to measure the lunar distances. This founded the movement to determine longitude by astronomy and led to the state-funding of observatories at Greenwich and Paris, the invention of the chronometer by JOHN HARRISON, and the accurate measurement of star positions and planetary orbits.

Westerbork Synthesis Radio Telescope

The WSRT (Westerbork Synthesis Radio Telescope) in Hooghalen, The Netherlands, is an aperture synthesis interferometer that consists of a linear array of 14 antennas arranged on a 3 km east–west strip. The array works by combining the signal from all the antennas and simulates a 3 km aperture telescope.

The antennas are equatorially mounted 25 m dishes with an f/D ratio of 0.35. This type of mounting ensures a fixed orientation of the receiving systems with respect to the sky. Ten of the telescopes are fixed, 144 m apart, while two nearby dishes are movable along a 300 m track and two others are on a 180 m track at a distance of 1.5 km. In the array, the baselines extend from 36 m to 3 km. The pointing accuracy of the dishes is 15 to 20 arcseconds, the surface accuracy is of the order of 1.7 mm.

The WSRT telescope with the first 12 antennas on a 1.5 km baseline was inaugurated in 1970. The second phase with two antennas on the 3 km extension was completed in 1980. A major upgrade due to be finalized in 2000 has added multi-frequency front ends capability and new state-of-the-art backends. The array can routinely operate at 92, 49, 21, 18, 13, 6 and 3 cm wavelength and change frequency in less than a minute. An observing capacity with instantaneous bandwidth up to 160 MHz is being added.

The WSRT is used by astronomers from The Netherlands but also from many other countries for a wide range of scientific research starting from our Galaxy to objects at the far reaches of the universe. There are two proposal deadlines each year. The WSRT also participates in the European (EVN) and Global Very Long Baseline Interferometry networks.

The WSRT is operated by the Netherlands Foundation for Research in Astronomy (NFRA), which is funded by the Netherlands Organization for Scientific Research (NWO).

Whipple, Fred Lawrence (1906–)

Astronomer, born in Red Oak, IA, became director of the Smithsonian Astrophysical Observatory. While still a graduate student he helped compute the orbit of newly discovered Pluto. Using a new method of photography from two separated wide-angle cameras, he triangulated on meteor tracks and determined their orbits. He deduced that nearly all are made up of bits from comets. He proposed the 'dirty snowball' model for comets, suggesting that comets have icy cores inside layers of dirt. This was confirmed in 1986 when the Giotto spacecraft flew near to, and imaged, Comet Halley. Whipple tracked artificial satellites to determine the shape of the Earth.

Whirlpool Galaxy

A face-on, spiral galaxy, M51, which derives its name from its bold and clear-cut spiral pattern. Located at a distance of some 20 million light-years in the constellation of Canes Venatici, M51 (also known as NGC 5194), which has two well-defined arms that spiral out from its relatively small central bulge, is a classic example of a 'grand design' spiral. It is classified as an Sc galaxy in the Hubble classification scheme. Although, with a diameter of 65 000 light-years and a mass of about 5×10^{10} solar masses, it is somewhat smaller than the Milky Way Galaxy, it is several times more luminous, its spiral arms being laden with bright young clusters and HII regions.

M51 has a smaller, fainter companion (NGC 5195), which lies at the end of one of the larger galaxy's spiral arms. Although NGC has traditionally been classified as an irregular galaxy, it contains an elongated bar structure and hints of incipient spiral arms. NGC 5194 appears to be orbiting around M51 in a period of about 500 million years. Tidal interaction between the two, during their last close encounter, which took place some 70 million years ago, probably played a large part in establishing the bold spiral pattern in M51 and stimulating a vigorous bout of star formation within it.

M51 was the first galaxy to be recognized as having a spiral shape. This discovery was made in 1845 by William Parsons (1800–67), third Earl of Rosse, with the aid of the 1.8 m (72 inch) telescope that he had set up at Birr, in Ireland, and which, at that time, was the largest telescope in the world.

Whiston, William (1667–1752)

Born in Norton, Leicestershire, became the controversial third Lucasian Professor of Mathematics at Cambridge University, succeeding ISAAC NEWTON. He used the principles of the *Principia* in a popular book to explain the Book of Genesis and the Flood, which he envisaged as caused by the near approach of a comet, an interesting foreshadowing of current theories. He published in 1716 the first undergraduate course based on Newton's principles under the cumbersome title *Sir Isaac Newton's Mathematic Philosophy More Easily Demonstrated with Dr. Halley's Account of Comets Illustrated*. He wrote on numerous problems of astronomy and observed an aurora borealis, solar eclipses and sunspots. His downfall in the so-called Whiston's affair was due to his popularization of what were regarded as heretical ideas about the Trinity, theology and politics. He wrote letters to archbishops that raised eyebrows, caused debates in the Houses of Parliament and caused his dismissal from his post. Plunged into poverty, he lived off the income of a small farm near Newmarket and lectured in the coffee houses of London, giving scientific demonstrations for a fee as an entertainment.

White Dwarfs

White dwarf stars, also known as degenerate dwarfs, represent the endpoint of the evolution of stars with initial masses ranging from about 0.08 to about 8 solar masses. This large range encompasses the vast majority of stars formed in our Galaxy and thus white dwarf stars represent the most common endpoint of STELLAR EVOLUTION. It is believed that over 95% of the stars of our Galaxy will eventually end up as white dwarfs. The defining characteristic of these objects is the fact that their mass is typically of the order of half that of the Sun, while their size is more akin to that of a planet. Their compact nature gives rise to large average densities and surface gravities.

The first glimpse of the existence of these objects came in 1844, with the study carried out by F BESSELL, the great German mathematician and astronomer, of the proper motion of SIRIUS, the brightest star in the night sky. The irregularities in the apparent motion of Sirius on the celestial sphere led Bessell to suggest the presence of an unobserved, solar-mass companion orbiting the bright primary. The companion, Sirius B, was first observed by A G Clark in 1862 and represents, together with 40 Eri B, the first known examples of white dwarf stars.

The luminosity of the white dwarf in the Sirius system is ∼10 000 times smaller than that of its bright, main-sequence companion. Its effective temperature was thus thought to be suitably smaller than that of the A star. However, the first spectrum of Sirius B, secured by W Adams in 1914, showed that the white dwarf had an effective temperature quite comparable with that of its companion. Since the stellar luminosity scales as $R^2T_{\rm eff}^4$, for the white dwarf to be both fairly hot and quite faint required it to have a very small radius, and a correspondingly very high average density. A similar conclusion was reached in the case of 40 Eri B whose spectrum was also secured at about the same time. However, how could such stars withstand the tendency to collapse onto themselves under the influence of their gravitational field?

The answer to that question came in 1925, when R H Fowler first applied the newly-developed principles of QUANTUM MECHANICS to stars. He showed that, in white dwarf stars, the density is high enough for the gas of free electrons to become degenerate. Electrons are said to be degenerate when a majority of them occupy the lowest possible energy states available to them. This occurs, at fixed temperature, when the electrons are packed sufficiently close to each other. Because of the PAULI EXCLUSION PRINCIPLE that no more than two electrons with oppositely directed spins may occupy the same energy state, the electrons retain kinetic motions even when cooled to zero temperature. The amplitude of this kinetic activity increases with increasing density, when electrons become more degenerate. In a white dwarf, the pressure generated by this kinetic motion, clearly of quantum mechanical origin, prevents the gravitational collapse of the star. The first detailed stellar models appropriate to white dwarfs were calculated in the 1930s by S Chandrasekhar, who received the 1983 Nobel Prize in Physics for his achievements.

Observed properties

Several properties of white dwarf stars can be determined fairly directly from observations. Analyses of their energy distribution, as well as of their optical and ultraviolet spectra, fix their effective temperature; they range from ∼150 000 K for the hottest stars to the coolest degenerate dwarfs, at $T_{\rm eff}$ near 4000 K. Spectroscopic analyses also yield the surface gravity ($g = GM/R^2$, but traditionally given in terms of its logarithm to the base 10, $\log g$) since the strength and width of spectral features are sensitive to the density of particles in the atmosphere, which is controlled by the surface gravity. The average surface gravity of white dwarf stars is $\log g \sim 8$ (cm s^{-2}), compared with $\log g \sim 4.4$ for the Sun. This value implies, as we discuss below, that the mean STELLAR MASS must be of the order of half that of the Sun. The luminosity range encompassed by white dwarfs exceeds 7 orders of magnitude and reflects the large range of observed effective temperatures ($L \propto T_{\rm eff}^4$); the faintest known white dwarfs have $L \sim 10^{-4.3} L_\odot$, while the rare intrinsically brighter ones, just entering the cooling sequence, reach $L \sim (10^2$–$10^3) L_\odot$.

Because of the intrinsic faintness of the most common white dwarfs, the observation of these objects tends to be restricted to small distances; the bulk of the sample of ∼2200 spectroscopically confirmed white dwarfs available today resides within ∼1 kpc from the Sun. It must be noted, however, that work with large, ground-based telescopes and with the Hubble Space Telescope now allows the observation of white dwarfs in GLOBULAR CLUSTERS located at several kpc from the Sun. Traditionally, however, white dwarfs have been culled from samples of objects showing significant PROPER MOTION, and thus located relatively nearby the Sun. A selection criterion based on color then allows the distinction to be made between true white dwarfs and nearby main-sequence stars, and their degenerate nature is then confirmed through spectroscopic observations. More recently, large numbers of hot white dwarfs have been detected in colorimetric searches. Selected fields are typically photographed through both U (∼3650 Å) and B (∼4400 Å) filters. A comparison of both images for a given object allows the selection of blue or very blue objects, whose nature can be confirmed through spectroscopic means. Surveys of this kind, carried out both at high Galactic latitude and in the plane of the Galaxy, have yielded substantial numbers of new hot white dwarfs, selected only on the basis of their colors without regard for their proper motion.

The existence of homogeneous samples containing substantial numbers of white dwarfs allows analyses of the statistical properties of these objects. Their distribution in the Galaxy is consistent with that of an old disk population, with an estimated scale height of 250–300 pc. Their space density is of the order of 0.005 pc^{-3} for $M_{\rm bol} < 15$, and their

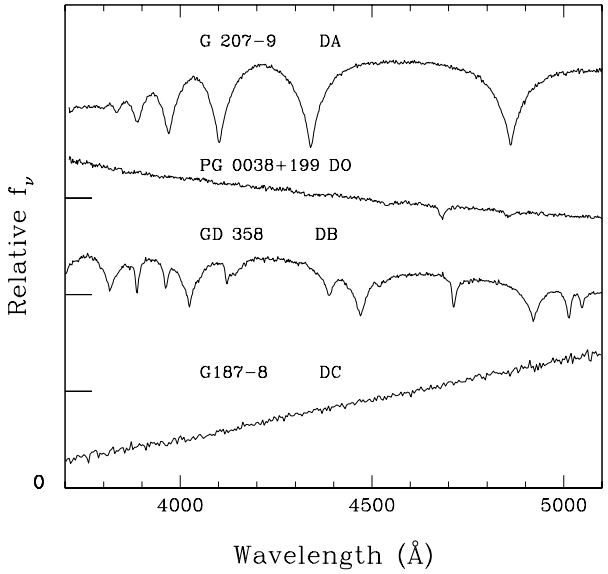

Figure 1. Sample optical spectra of white dwarf stars: from top to bottom, a DA spectrum, dominated by the regular pattern of the Balmer lines of hydrogen, seen here near their maximal strength, a DO spectrum, dominated by the lines of ionized helium, in particular the $n = 3$ to $n = 4$ transition at 4686 Å, a DB spectrum, featuring many strong lines of neutral helium, and a featureless DC spectrum, characteristic of a helium-rich star too cool ($T_{\rm eff} < 12\,000$ K) to show neutral helium lines.

birthrate is of the order of $(1.5\text{–}2.3)\times10^{-12}$ pc^{-3} yr^{-1} when allowance is made for the contribution of unseen white dwarfs in BINARY SYSTEMS.

The optical spectra of white dwarf stars are characterized by a rich variety which reflects, to a considerable extent, complex and varying patterns of atmospheric abundances. Sample spectra are shown in figure 1. About three-quarters of white dwarfs have a spectrum dominated by the Balmer series of hydrogen, which originates on the first excited, or $n = 2$, level of that atom. These objects are termed DA stars; they are found over the whole effective temperature domain of white dwarfs, from the very hottest stars above 100 000 K, where the hydrogen lines are fairly shallow, to the coolest white dwarfs near 4000 K, where the lines are sharp and extremely weak. Another important group of objects have optical spectra dominated by the lines of helium. The spectrum reflects the vastly different chemical makeup of their atmosphere, which is dominated by helium. At high effective temperatures ($T_{\rm eff} > 45\,000$ K), the lines observed are those of ionized helium. These stars are called DO stars. Between 30 000 K and 12 000 K, neutral helium is the dominant ion, and the spectrum is dominated by a bevy of transitions from that atom; these are the DB stars. Finally, below 12 000 K, the effective temperature is too cool for a helium-rich atmosphere to show transitions of neutral helium; the spectrum is then featureless, and is termed DC.

The scheme of spectral classification of white dwarfs is flexible enough to accommodate several other important classes of objects, not illustrated in figure 1; hence the DQ stars, whose spectrum is characterized by the presence of carbon, generally in molecular form, in a helium-rich atmosphere too cool to show lines of neutral helium. Similarly, the DZ stars show lines of heavy elements other than carbon, for example calcium, magnesium or iron. Sometimes, the star is hot enough for weak carbon or heavy element features to be present simultaneously with the dominant neutral helium lines: the stars are then classified DBQ or DBZ stars, respectively. At high effective temperatures, near $T_{\rm eff} \sim 100\,000$ K, another class of objects, termed PG 1159 stars, includes stars with spectra featuring ionized helium as well as highly ionized carbon and nitrogen features.

As hinted above, the chemical composition of the atmosphere of a white dwarf star is intimately related to its spectral appearance. The hydrogen line DA stars have atmospheres where hydrogen is the dominant element, to the near complete exclusion of any other. For their part, the so-called non-DA stars, which encompass objects of the DO, DB, DC, DQ and DZ spectral types, all have helium-dominated atmospheres. Within both classes, this purity is understood today as the result of gravitational settling in the intense gravitational field of the white dwarf. Under its influence, all elements heavier than the dominant atmospheric constituent rapidly sink into the deep atmospheric layers of the stars and remain out of sight. In fact, this settling mechanism is so efficient that the presence of any element heavier than hydrogen in the atmospheres of DA stars, or helium in those of non-DA stars, constitutes a puzzle. For example, lines of heavy elements (in the DAZ stars) or of helium (in the DAB stars) are occasionally seen in DA stars at effective temperatures below 25 000 K. Similarly, traces of heavy elements are observed in the DBZ and cooler DZ stars, while carbon is seen in the cool DQ stars. We discuss below the mechanisms which may permit the existence of such chemical impurities in the photospheres of white dwarfs.

Another point of interest for white dwarfs is their mass distribution. Only in a handful of cases are direct, dynamic masses obtained for these stars. In general, surface gravities are obtained either from the optical colors (e.g. on the Strömgren *uvby* system, suitable for DA stars with effective temperatures between 16 000 K and 8000 K) or, preferably, from optical spectra which tend to be more sensitive to surface gravity. The M/R^2 relation provided by the log g determination can then be coupled to an assumed mass–radius relation, characteristic of the mechanical structure of these stars (see below), to determine M. The mass distributions (based on optical spectroscopy) available for samples of two spectroscopic subclasses of white dwarfs are shown in figure 2. The mass distribution of the DA stars is sharply peaked, and the mean mass is $M = 0.590 M_\odot$, with a dispersion $\sigma = 0.134 M_\odot$. Tails extend at both ends of the mass spectrum: the low-mass tail of the distribution is thought to be

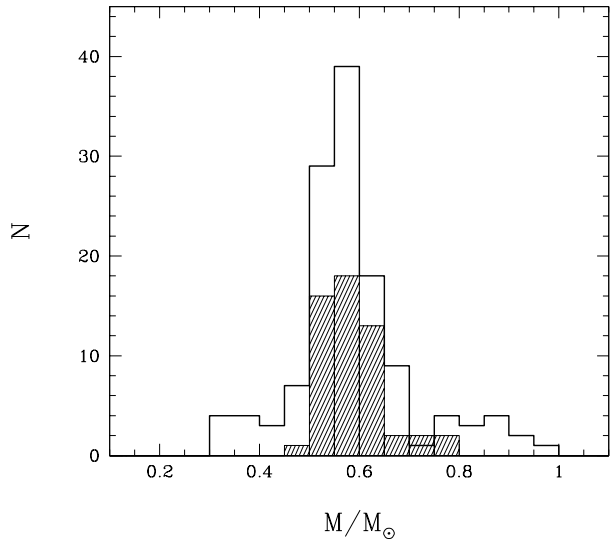

Figure 2. Mass distribution of DA (thick outline) and DB (shaded area) white dwarfs. The average mass appears the same, but the DB sample studied seems to lack both the low-mass and the high-mass end of the distribution seen for DA stars. These wings are probably related to binary evolution.

populated by low-mass white dwarfs with helium cores probably resulting from binary and common envelope evolution, whereas the high-mass tail could well be the result of merging events in binary systems. Nevertheless, the case of Sirius B ($M = 1.05M_{\odot}$), located in a wide binary system, shows that there are genuine high-mass white dwarfs which have not been produced by close binary evolution. It is worth noting, as well, that independent mass determinations for roughly three dozen DA stars can be obtained from the gravitational redshift of their Balmer lines. General relativity predicts that the wavelength of photons emitted in a strong gravitational field should be redshifted by an amount $\Delta\lambda$ which depends on the M/R ratio. Provided that the star under scrutiny belongs to an open cluster or a binary system with a well-determined radial velocity, and that the spectral line shifts induced by the high pressures of white dwarf photospheres are well understood, the gravitational redshift can be isolated, and the mass can be determined.

The mass distribution of the DB stars, while based on a smaller sample of well-studied objects, shows at the very least that there are no substantial differences between the mean mass of the DA and of the DB stars (the latter being $M = 0.585M_{\odot}$, with a dispersion $\sigma = 0.063M_{\odot}$). There is a tantalizing suggestion, however, that the low-mass and high-mass tails present in the DA sample may not be present in the DB sample; this absence accounts for the smaller dispersion of the DB mass determination.

While most of the white dwarfs identified today can be considered normal, garden-variety objects, two families of peculiar, and fascinating, white dwarfs have also emerged over the years. One such family is that of the magnetic objects, which currently includes nearly 50 stars. The detected magnetic fields range from 10^5 G all the way to 10^9 G and are measured through a variety of techniques which include the detection of circular polarization in the optical continuum ($B_e \geq 10^7$ G), the direct observation of the Zeeman pattern in absorption lines (10^6 G $\leq B_e \leq 10^7$ G), and Zeeman spectropolarimetry for low fields ($B_e \leq 10^6$ G). In the high-field objects, the spectrum is so perturbed by the magnetic field that spectroscopic classification is often difficult if not impossible. The inferred field morphologies tend to be rather simple and generally range from centered or offset dipoles to quadrupoles. Statistical arguments favor an evolutionary link between the chemically peculiar main-sequence Ap and Bp stars and the magnetic white dwarfs. The other distinct subgroup of interesting white dwarfs is that of the variable white dwarfs, or pulsators, examples of which are known among the hot PG 1159, the DB and the DA stars. The usefulness of these objects for our sounding of the internal structure of white dwarfs is discussed briefly below, as well as in the entries on ZZ CETI STARS and DB PULSATING STARS.

Perhaps somewhat surprisingly, white dwarfs appear to be slow rotators, in the sense that they rotate more slowly than would be expected if the ANGULAR MOMENTUM present in earlier evolutionary phases had been conserved. Determinations of the rotation velocity of white dwarfs rely on three different techniques: (i) measurement of the additional broadening of the core of absorption lines caused by rotation; (ii) measurement of the variation of the degree of circular polarization caused by rotation in magnetic white dwarfs; (iii) measurement of the rotational splitting present in the Fourier spectrum of the light curves of pulsating white dwarfs. While the use of any of these techniques is restricted to small subsamples of white dwarfs, the picture which emerges is one where substantial quantities of angular momentum must have been lost by stars on their way to the white dwarf stage. While no definite model exists to explain this loss, current ideas focus on the fact that most stars will need to shed a lot of mass, perhaps concomitant with angular momentum, before they do become white dwarfs.

Origin and generic properties

It is generally believed that the immediate progenitors of most white dwarfs are nuclei of PLANETARY NEBULAE, themselves the products of intermediate- and low-mass main-sequence evolution. As mentioned above, stars that begin their lives with masses less than about $8M_{\odot}$, that is the vast majority of them, are expected to become white dwarfs. Among those which already have had the time to become white dwarfs since the formation of the Galaxy, a majority have burned hydrogen and helium in their interiors. Consequently, most of the mass of a typical white dwarf is contained in a core made of the products of helium burning, mostly carbon and oxygen. The exact proportions of C and O are unknown because of uncertainties in the nuclear rates of helium burning.

The observed narrow mass distribution of isolated white dwarfs discussed above is a remarkable property of this category of stars. Apparently, the process of mass loss in white dwarf progenitors, which may have a wide range of initial masses, is regulated by mechanisms that are tuned finely enough to leave remnants with similar masses consistently. Also, the empirical evidence suggests that small amounts of helium and hydrogen are left over after the mass-loss phases have subsided. Taking into account previous thermonuclear history and the efficiency of gravitational settling, the expected structure of a typical white dwarf is that of a compositionally stratified object with a mass of $\sim 0.6 M_{\odot}$ consisting of a carbon–oxygen core surrounded by a thin, helium-rich envelope itself surrounded by a hydrogen-rich layer. Such an object has an average density of $\sim 10^6$ g cm^{-3}, a millionfold that of a normal star such as the Sun. The thicknesses of the hydrogen and helium outer layers are not known *a priori* and must depend on the details of pre-white-dwarf evolution. On theoretical grounds, however, it is expected that the maximum amount of helium that can survive nuclear burning in the hot planetary nebula phase is only 10^{-2} of the total mass of the star and that the maximum fractional amount of hydrogen is about 10^{-4}. Although these outer layers are very thin, they are extremely opaque to radiation and regulate the energy outflow from the star. They consequently play an essential role in the evolution of a white dwarf. The question of the exact masses of the hydrogen and helium layers present in white dwarfs constitutes a topic of intense research interest in the field.

The large opacity of the outer layers of a white dwarf implies that radiation escaping from the star originates from the outermost region—the atmosphere—which contains, typically, less than 10^{-14} of the total mass of the star. Spectroscopic and photometric observations can only probe these outer regions, which are usually dominated by hydrogen. Thus, a majority of white dwarfs are referred to as hydrogen-atmosphere objects (or DA stars as discussed above). It turns out, however, that about 25% of the known white dwarfs do not possess such a hydrogen layer. These are called helium-atmosphere white dwarfs (or non-DA stars) with, again, the understanding that the underlying carbon–oxygen core must contain essentially all of the mass, even though it is not directly observable.

Mechanical structure and cooling

As former nuclei of planetary nebulae, most white dwarfs are born in the form of extremely hot, collapsed objects which can only cool off: their nuclear energy sources are depleted, and gravitational energy can no longer be tapped efficiently as degenerate electron pressure prevents additional contraction. Because this pressure is independent of the temperature, a white dwarf is condemned to evolve at essentially constant radius. The mechanical structure of such a star is therefore specified by the degenerate electrons. In particular, electron degeneracy is directly responsible for the curious relationship between the mass and the radius of a white dwarf: the more massive the star, the smaller its size is. Likewise, relativistic degeneracy is also responsible for the existence of a limiting mass above which a white dwarf cannot exist. This limiting mass is known as the Chandrasekhar mass, and is of the order of $1.4 M_{\odot}$. The effects of this peculiar mass–radius relationship are apparent in the diagram presented in figure 3 which shows the cooling tracks of five representative DA white dwarf models that differ in their total mass.

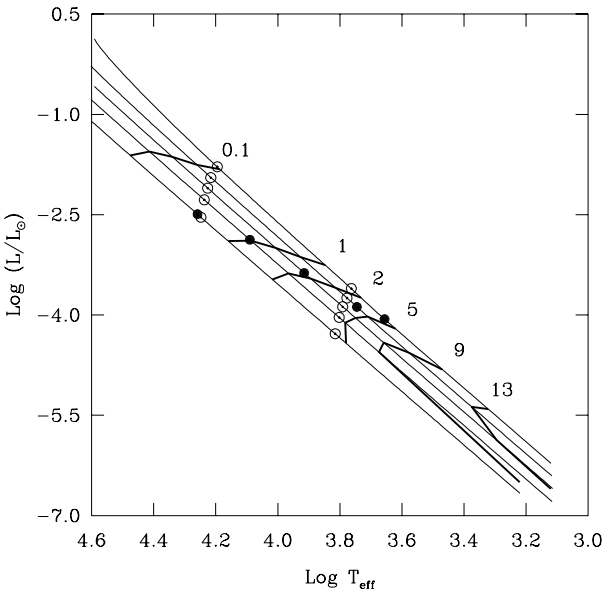

Figure 3. Evolutionary tracks (solid curves) of five ($M = 0.4 M_{\odot}$, $0.6 M_{\odot}$, $0.8 M_{\odot}$, $1.0 M_{\odot}$ and $1.2 M_{\odot}$, from top to bottom) representative models of DA white dwarfs in the Hertzsprung–Russell diagram. Each model is a compositionally stratified object made of a pure carbon core surrounded by a pure helium envelope containing 10^{-2} of the total mass of the star and an outermost pure hydrogen layer containing 10^{-4} of the total mass. The thick solid curves are isochrones, that is, loci of constant evolutionary timescales. The number next to each isochrone gives the cooling time in units of 10^9 yr. The small filled circles indicate the onset of crystallization at the center of each evolving model. The open circles at high (low) luminosity indicate the onset of superficial convection (the convective coupling of the surface with the thermal core).

Degenerate electrons also possess another property of high relevance for white dwarfs: they are excellent conductors of heat, and thus they thermalize the internal regions of white dwarfs efficiently (a familiar illustration of this property is provided by the conduction electrons in ordinary metals). We can thus envision a typical white dwarf as consisting of a nearly isothermal core that contains more than 99% of the mass, surrounded by a thin, opaque, insulating, nondegenerate outer envelope. In the range of effective temperatures 16 000–8000 K, where the bulk of the known white dwarfs is found, core temperatures vary from $\sim 2 \times 10^7$ K to $\sim 5 \times 10^6$ K. The very large temperature drop between the central regions

and the surface takes place mainly in the stellar envelope. In the cooler models, this temperature gradient leads to the formation of superficial convection zones, similar to those found in the Sun. When present, atmospheric convection plays an essential role in the determination of the emergent flux from a white dwarf and, thus, in the interpretation of its spectrum and colors. The small open circles at high luminosity in figure 3 show the onset of a superficial convection zone due to the recombination of hydrogen in evolving models of DA stars. Convection plays also a key role in the subsequent evolution of a white dwarf by affecting directly the cooling rate. This occurs when the base of the superficial convection zone reaches into the degenerate interior, thus coupling the surface with the core and, thereby, increasing the rate of energy transfer across the outer opaque envelope beyond what is possible through radiative transfer alone. The small open circles at low luminosity in figure 3 show where convection starts to play a significant role in the cooling process.

Largely decoupled from the electrons, the (nondegenerate) ions provide the thermal energy that slowly leaks through the outside, thereby producing the star's luminosity. Thus, an isolated white dwarf shines at the expense of its thermal reservoir. In this context, the electrons do not contribute significantly to the energy reservoir because degenerate particles, already occupying their states of lowest energy, cannot be cooled. As thermal energy is gradually lost from the star in the form of radiation, the kinetic motions of the ions lose amplitude, become correlated, and the ionic state evolves from a gas to a fluid to a solid. Ultimately, the reservoir of thermal energy becomes depleted, and the star disappears from sight in the form of a cooled-off, crystallized object known as a black dwarf.

It should be noticed that the timescale for this final demise is strongly dependent on the total mass of the white dwarf. Indeed, because of their larger masses and smaller radii, more massive stars have larger internal densities (for comparable temperatures) and, therefore, develop a crystallized core earlier, at higher luminosities. By the same token, they also reach earlier the state where the specific heat in the solid regime plunges to very small values, a phenomenon well explained within the framework of the simple Debye theory of solids in quantum statistical mechanics. In effect, matter under these conditions has lost its ability to store thermal energy, the energy reservoir of the white dwarf has become empty and the star must then disappear from sight in a relatively rapid and final phase sometimes referred to as 'Debye cooling'. Figure 3 illustrates, among other things, how Debye cooling is a strong function of the total mass of the white dwarf. It is easily seen that the isochrones are strongly dependent on the total mass; crystallization and subsequent Debye cooling are responsible for the 'accelerated' evolution of the more massive models at low luminosities. To complement this, figure 4 provides more details on the evolving structure of a representative white dwarf model in a phase diagram.

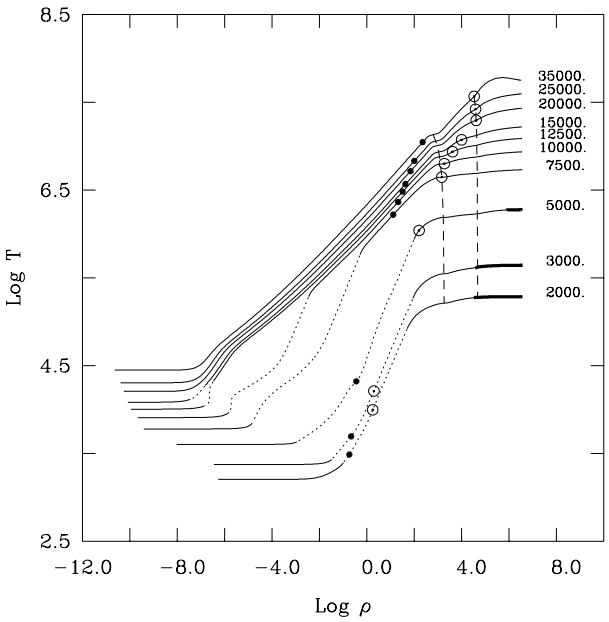

Figure 4. Evolving structure of a representative model of a DA white dwarf in a phase diagram. This is one ($0.6M_{\odot}$) of the five models presented in the previous figure. Each curve corresponds to the density–temperature distribution from the surface to the center of the model at an effective temperature given by the number alongside. The solid, dotted, and thick solid (for the three cooler epochs) portions of each curve indicate the radiative–conductive, convective and crystallized regions. Electrons become degenerate to the right of the small filled circle on each curve. Likewise, the small open circle on each curve indicates the location where the ions become strongly correlated (fluid phase). The dashed curves define the composition transition zones, H–He at lower densities, and He–C at higher densities.

A final point about the cooling evolution of white dwarfs should be made. In the early, short-lived phase of evolution following immediately the planetary nebula phase, white dwarf interiors are still hot enough that NEUTRINOS can be formed in great quantities there through a number of processes involving the electromagnetic and the weak interactions. The vast majority of the neutrinos escape directly from the central regions where they are created to the outer space, thus contributing to an important stellar energy sink. For instance, neutrino luminosities may become 2 orders of magnitude larger than photon luminosities in these objects. The evolution of a very hot, young white dwarf is thus dominated by neutrino cooling. Neutrino processes largely specify the cooling timescale and lead as well to a temperature reversal in the stellar core. Such a reversal is still visible in the hotter model shown in figure 4. By the time a white dwarf has cooled down to $T_{\rm eff} \sim 25\,000$ K, however, the star has lost its memory of the neutrino cooling phase, and its subsequent evolution and structure depend exclusively on the properties of its degenerate electrons and thermal ions.

It should be clear from this discussion that there

exists an intimate relationship between dense-matter physics and the structure and evolution of white dwarfs. For instance, a detailed knowledge of the opacity and thermodynamics of strongly coupled plasmas is necessary to compute the cooling rate of a white dwarf. Indeed, this rate basically depends on how much thermal energy is stored in the interior of a star and how rapidly this energy is transferred from the hot core to the cold interstellar medium through the thin, opaque outer layers. Hence, a reliable description of the constitutive properties of dense plasmas is required to build a *theory* of evolving white dwarfs. By the same token, the *observed* properties of cooling white dwarfs can be used, in principle, to test theories of strongly coupled plasma physics.

Spectral evolution

There is strong observational evidence that spectral evolution takes place among white dwarfs, that is, some of the hydrogen-atmosphere stars become helium-atmosphere objects, and vice versa, during various evolutionary phases. Indeed, the ratio of DA to non-DA white dwarfs changes as a function of effective temperature along the cooling sequence. In particular, the cases for the existence of a so-called DB gap—an interval of effective temperature from 45 000 K to about 30 000 K in which *no* helium-atmosphere object has been found—and of a cooler and narrower non-DA gap between ∼6000 K and ∼5000 K are well documented. Completely convincing explanations for these phenomena (especially in the case of the cooler gap) have not been worked out yet, but the very existence of 'holes' in the distribution of helium-atmosphere objects as a function of effective temperature is a strong empirical proof that, at least, some of the white dwarf stars must change their superficial chemical composition from helium-dominated to hydrogen dominated and back to helium rich again as cooling proceeds. It is suspected that a complex interplay between mechanisms such as hydrogen and helium separation (through diffusion) and convective dilution and mixing is responsible for the fact that a white dwarf may show two different 'faces' along its cooling track. For example, in DA stars below 15 000 K, convective mixing is thought to be effective in bringing deep-lying helium to the surface and drastically changing the surface composition. Unfortunately, at these effective temperatures, the helium brought to the surface is spectroscopically invisible, and its presence must be inferred through rather indirect analyses. The case for spectral evolution is further strengthened by another observational datum of importance: as pointed out above, there is no significant difference between the mass distribution of DB white dwarfs and that of the DA white dwarfs, excluding those objects that have been formed through binary evolution. This is what one would expect for stars changing only surface compositions. This being said, while spectral evolution appears unavoidable, it cannot currently explain all the peculiarities of the abundance patterns observed in white dwarfs. Alternative schemes, for example different channels feeding the cooling sequence, should be considered in order to account completely for the rich variety of spectral types.

White dwarf stars are not only unusual in that the abundance of their main atmospheric constituent (hydrogen or helium) may change in a complex way as a function of time, but they also show an amazing variety of heavier trace elements in their atmospheres, arguably making them the most fascinating of all chemically peculiar stars. This is because the cooling phase of white dwarfs, a relatively uneventful phase from an evolutionary point of view as discussed above, is, in contrast, a most active phase for the evolution of the chemical composition of the envelope. Indeed, it is now well established that the often puzzling variety of surface abundances observed in white dwarf stars can be traced to the simultaneous operation, in the outer layers of these stars, of a variety of physical processes which will also erase the abundances present in the photosphere at the onset of cooling. As discussed above, downward element diffusion in the intense gravitational field of a degenerate star is perhaps the mechanism which is the most closely identified with white dwarf stars. However, in its presence, the observed abundances of various atmospheric impurities, while small, are much too large to be accounted for.

Mechanisms which compete with the downward settling must thus be called on to explain the presence of these impurities in the atmospheres. At high effective temperatures, say $T_{\rm eff} > 20\,000$ K, the dominant competing mechanism is thought to be the selective radiative support of elements in the atmosphere. This mechanism, which involves the transfer of momentum from the intense radiation field to ions of heavy elements such as carbon, nitrogen, silicon, iron and helium, is able to counteract the downward gravitational force exerted on these ions and allows a small, but measurable, amount of impurities to remain in the atmosphere. Unfortunately, detailed calculations of this radiative support still do not reproduce the observed abundances, and it is currently thought that a small mass loss rate (of the order of $\sim 10^{-13} M_{\odot}$ yr^{-1}), when coupled to radiative levitation, might be able to account for the observed abundance patterns. For cooler stars, it is believed that ACCRETION from the interstellar medium plays a role in accounting for the traces of heavy elements occasionally seen. Individual accretion events, probably related to encounters between a white dwarf and a small patch of neutral gas in the interstellar medium, might be able to account for the small fraction of DA and non-DA stars which display impurities in their spectra. In the DQ stars, it is thought that the convection in the helium envelope is deep enough to dredge up traces of carbon from the deeper carbon-rich layers. Much energy has been expended, in the last two decades, to untangle the relative importance of these competing mechanisms and to decipher the complex patterns of photospheric abundances observed in white dwarfs. Nevertheless, much work remains to be done.

Some areas of current interest

In the era of the Hubble Space Telescope and of giant, 8–10 m ground-based telescopes, faint white dwarf populations are being routinely discovered and studied in open and globular clusters. In addition, evidence has been provided for the existence of a very old, faint population of white dwarfs in the Galactic halo on the basis of an interpretation of some MICROLENSING events and, more directly, on the basis of the observed proper motions of some very faint objects in the HUBBLE DEEP FIELD whose positions in a color–magnitude diagram are consistent with very cool ($T_{\rm eff} \sim$ 2000–3000 K) DA white dwarfs. These exciting developments have led to a renewed interest in white dwarf cooling calculations and model atmosphere calculations using upgraded input physics and extending into the regime of very low effective temperatures. Such efforts are clearly worthwhile since white dwarf physics holds the potential for providing the best indicators of the ages of, and distances to, these systems.

The usefulness of white dwarfs as cosmochronometers was firmly established about a decade ago when it was first demonstrated that the white dwarf population in the solar neighborhood—a population characteristic of the Galactic disk—could be used to estimate the age of the disk to much improved accuracy. This method applies because (intrinsically) faint white dwarfs cool down extremely slowly (see the isochrones in figure 3). This implies that, if white dwarf formation has been going on more or less constantly over the distant past, many more faint white dwarfs than bright white dwarfs should be present in a given volume of space. This is indeed what the distribution of observed white dwarfs in the Galactic disk generally shows (figure 5). However, a very important and significant observational result of the last decade has been the realization that there is a significant decrease in the luminosity distribution of these stars: there is a real deficit of low-luminosity white dwarfs in the solar neighborhood. The simplest model to account for this observational fact is to assume that the oldest white dwarfs in the Galactic disk are still visible. In other words, the corpses of the very first generation of intermediate-mass stars formed in the disk of the Milky Way have not yet had the time to cool to invisibility, beyond the reach of our telescopes. By comparing the location of the observed low-luminosity decrease in the white dwarf distribution with cooling calculations, it is possible to infer the age of the white dwarf population in the Galactic disk (see figure 5 for an example of this). While the method continues to be refined through numerous numerical simulations of evolving white dwarfs in the context of the Galactic disk, its potential for the white dwarf populations in open and globular clusters as well as for the putative population in the Galactic halo is evident.

Another area of current active interest is related to the presence of so-called instability strips along the cooling sequences of white dwarfs in the HERTZSPRUNG–RUSSELL DIAGRAM. Helium-atmosphere white dwarfs become unstable against nonradial gravity-mode pulsations as they evolve through an interval of effective temperatures from ∼25 000 K to about ∼22 000 K. The instabilities are intimately connected to the recombination of helium in the envelopes of these stars and the concomitant formation of a superficial helium convection zone. There also exists an analogous instability strip for the hydrogen-atmosphere white dwarfs, related, this time, to the recombination of hydrogen in the outer layers, and, consequently, which is located at lower effective temperatures, in the range 12 500–11 000 K. In both cases, the pulsational instabilities manifest themselves as temperature waves at the stellar surface that cause multiperiodic luminosity variations. The pulsating DB white dwarfs are referred to as V777 Her stars, while their DA counterparts are known as ZZ Ceti variables. The importance of these two instability strips stems from the fact that they provide windows through which the internal structure of white dwarfs can be probed. For instance, a detailed comparison of the observed period structure of pulsating white dwarfs with those of models provides a unique way of inferring the internal constitution of white dwarfs and, in particular, the run of the chemical composition as a function of depth. Although the potential of this technique has been barely tapped, it is likely that asteroseismological studies of white dwarfs will soon become a major contributor to our knowledge of the internal structure of these stars. One of the major potential impacts of these studies is the determination of the thicknesses of the outer layers of helium and hydrogen (in

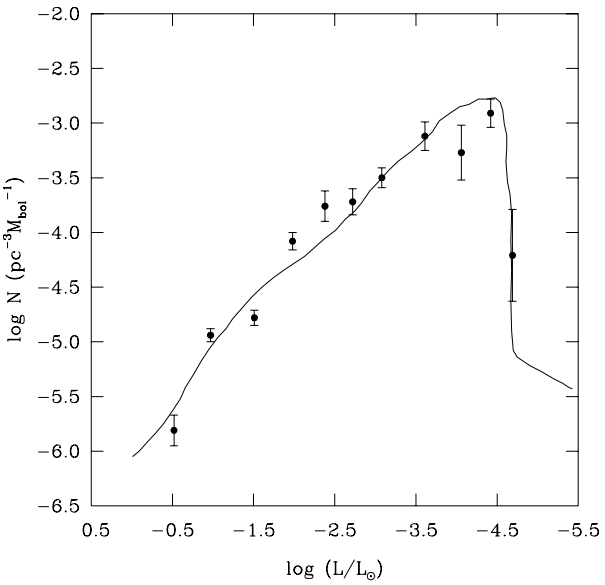

Figure 5. Luminosity function of white dwarfs in the solar neighborhood, that is the number of white dwarfs per unit volume per unit luminosity interval as a function of luminosity in solar units. The observed values are indicated by error bars. Note, in particular, the deficit of low-luminosity stars shown in the last bin. The solid curve is a fit to the data points based on cooling calculations which assume an age of 9.3×10^9 yr for the Galactic disk.

White Dwarfs in the Galaxy's Halo

The Galaxy's large spherical halo (see GALACTIC METAL-POOR HALO and HALO, GALACTIC) may harbor as many as several hundred billion WHITE DWARFS, a population as large in number as the total number of stars in the Galaxy's disk (see DISK GALAXIES and GALACTIC THIN DISK). Although this assertion is controversial, several astronomical surveys provide strong support for it and the implications affect fields of astronomical inquiry as diverse as dark matter and star formation. The reason that this population of white dwarfs may be related to dark matter is tied to the fact that white dwarfs cool and fade as they age. This means that a white dwarf as old as the ancient halo is extremely faint. Current large-scale imaging surveys can only see relatively nearby white dwarfs, and only a tiny fraction of the halo's mass exists near the Sun, while the vast majority of the Galaxy's halo is thousands of light-years away.

The theory of gravity requires that the mass of the halo must dominate that of the Galaxy's disk. Since the halo is largely invisible, it is almost entirely made of dark matter (see DARK MATTER IN GALAXIES). Indeed, the known population of normal stars in the halo constitutes a trivial fraction of the total mass. However, those stars exhibit properties distinct from disk stars, including rapid motion relative to the Sun. As a result a halo star that happens to be within the solar neighborhood can be distinguished from a disk star by examining the rapidity with which it passes through the solar neighborhood. This is a statistical criterion, meaning that for any given star one can assign a probability that it belongs to the disk or halo. For a survey of many stars with such probabilities one can estimate the actual number of stars in the disk and halo populations.

The first hint that white dwarfs may be a significant part of the halo emerged in 1996, when a group conducting a MICROLENSING experiment claimed to detect indirectly a large population of objects in the Galaxy's halo all with masses characteristic of white dwarfs. Instead of actually seeing the white dwarfs themselves, they observed the effect they have on images of stars in the Milky Way's companion galaxy the Large Magellanic Cloud (see WIMPS AND MACHOS). The microlensing results, now backed by several independent, similar experiments, have found that at most 20% of the total mass of the Galaxy's halo may be in this supposed population of white dwarfs.

In 2001 a search for moving stars in an archive of photographic plates taken between 1950 and 1998 revealed about 20 nearby white dwarfs which are moving so fast that they must be members of the Galaxy's halo. Statistical analysis of the data showed that at least 1% of the halo's mass is due to a population of white dwarfs. Alternative interpretations of this survey suggest that a fraction of this population may be part of the Galaxy's thick disk. In all of the interpretations, however, there still appears to be an unexpectedly large number of white dwarfs in the halo, constituting at least 0.5% of the halo's mass.

With 0.5–20% of the halo's mass accounted for by white dwarfs, a fraction of the Galaxy's dark matter has finally been identified. Furthermore, the halo white dwarf population is important to STAR FORMATION theory. Ongoing star formation creates many low-mass stars for every high-mass star. If the same proportions of high- and low-mass stars formed 13 billion years ago, when the halo formed, only one to five halo white dwarfs should have been found by the recent survey. This is known because the low-mass halo stars have not had enough time to evolve into white dwarfs, and we know the number of low-mass stars in the halo. That number, assuming a universal star formation process, determines the number of high-mass stars that have evolved into white dwarfs in the halo. The actual numbers observed imply that high-mass stars formed more readily in the halo than they do at present.

Whole Earth Telescope (WET)

A world-wide network of cooperating astronomical observatories which was established by astronomers from the University of Texas in 1986. WET HQ moved to Iowa State University in 1997.

Intended to obtain uninterrupted time-series measurements of variable stars (white dwarfs and Delta Scuti stars) and cataclysmic variables. This is done by resolving the multiperiodic oscillations observed in these objects into their individual components. The temporal spectrum allows astronomers to probe the interiors of the target objects using the technique of asteroseismology.

Since the first campaign in March 1988, the WET team has coordinated global photometry campaigns so that the target objects are visible from the night side of the planet 24 hours a day. These campaigns typically take place twice a year.

Widefield CCD Imagers

Since the early 1980s, the CHARGE-COUPLED DEVICE, or CCD, has emerged as the primary detector for astronomical observations. At the present time, CCDs are virtually the only detectors used for observations in the optical portion of the spectrum (300 nm–1000 nm), and their use has been extended into the UV (200 nm–300 nm) and x-ray (100 eV–10 keV) regions as well. Modern CCDs are superb detectors. When thinned and backside illuminated, and with new multilayer anti-reflection coatings, CCDs can offer quantum efficiency (QE) exceeding 70% and approaching unity over most of the optical waveband. The best CCD amplifiers now have readout noise below $2e^-$ rms and some have achieved the elusive $1e^-$ noise level. One of the main areas of development has been, and continues to be, in device size and pixel count. The very first CCD imagers had 100×100 pixels, while the first astronomically useful device was the RCA 320×512 with 30 μm pixels, followed by the 800×800 15 μm pixel device built by Texas Instruments for the WF/PC-I on the NASA HUBBLE SPACE TELESCOPE. As the 1990s began, the sizes of these devices began to grow. 2048×2048 pixel devices were produced by Ford Aerospace (which eventually became Loral, Loral/Fairchild, and now Lockheed-Martin) and Tektronix (now SITe). These 2K×2K pixel, and similar-sized, devices are now produced with good yields by several manufacturers.

The technical advances in ground-based instrumentation have included increases in telescope apertures and improvements in image quality and SEEING. It is not unusual to obtain $0''.5$ images or better at premier astronomical sites. Consequently, optics and detector systems must be designed with sufficient resolution to sample these sharp images, requiring that the detector pixels be no larger than $\sim 0''.25$. This requirement for small pixels, coupled with the need for large fields, drives the high pixel count needed in widefield imagers. For example, to be optimally sampled while spanning a $0^\circ.5 \times 0^\circ.5$ field requires that the array measure of order 8000×8000 pixels. In the near future, the image quality is likely to improve even more, driving the pixel sizes smaller and the pixel count higher in order to maintain the same field of view.

Monolithic devices are not suitable for such very large focal planes. Limitations in wafer size and yield set a practical limit to device size. In addition, other factors such as finite charge transfer efficiency (CTE) and readout time, as well as cost, must be considered when the number of pixels increases. In order to build the very large detectors needed to image wide fields of view at seeing-limited resolution, one must construct mosaics of smaller devices.

Large-gap CCD mosaic focal planes

The simplest approach to constructing a large mosaic focal plane is to mount large, packaged devices as tightly as possible on a common base. The resulting mosaic will have large gaps (1 cm or more) between the packaged CCD imagers that come from the wire bond pads that are required to make electrical connections to the silicon die and the wire bond pins that are usually located around the perimeter of the typical device package.

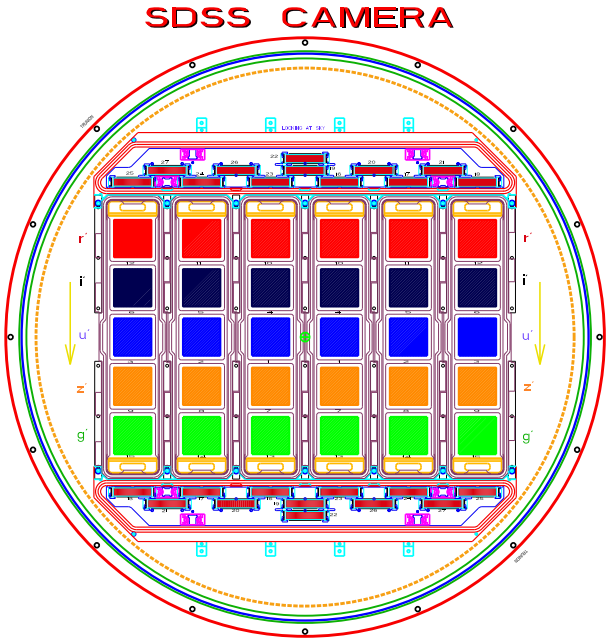

Figure 1. Drawing illustrating the layout of the SDSS CCD mosaic. The CCDs are arranged in six parallel columns each having five CCDs. Each CCD in a 'row' is covered by a different filter (ugriz). The imaged scene 'drifts' along the columns and the clocking of the charge is synchronized with the image motion. As a $2^\circ.5$ strip of sky is scanned, images in five colors are obtained from the camera. For this specialized application, the large gaps are not considered to be a serious problem.

Nevertheless, several widefield mosaic CCD imagers have been constructed using this technique, for example the 4K×4K pixel Big Throughput Camera constructed by the University of Michigan and Bell Labs, the 4K×8K mosaic imager built by the National Astronomical Observatory of Japan and the 10K×12K pixel camera built by Princeton University for the SLOAN DIGITAL SKY SURVEY (SDSS).

The SDSS camera (figure 1) consists of a 5×6 array of SITe 2K×2K CCDs with 24 μm pixels and is somewhat special in that it is designed to operate in the 'drift scanning' mode where the sky image is allowed to scan along the device columns while the accumulating photoelectron packets (or charge) are clocked to follow the image. This application differs from the conventional 'shift and stare' technique where the telescope is pointed at some region, an image is taken (typically only a few minutes integration), the telescope is shifted by an amount larger than the gaps separating the CCDs, another image is taken, and so on. The multiple images at different positions allow the gaps between the mosaic elements to be filled while also enabling the removal of cosmic rays that hit the device during the exposure.

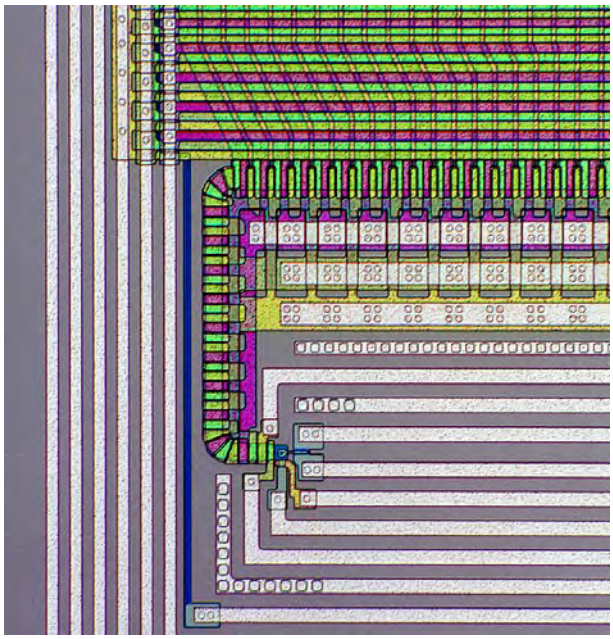

Figure 2. This photomicrograph of the lower left-hand corner of a three-edge buttable CCD illustrates several key design features for edge buttability. This particular device (a 2K×4K LL CCID-20 with 15 μm pixels) can be operated in framestore mode (if desired) so there are six metal bus lines distributing the three-phase parallel clocks to the imaging and storage regions. These can be seen as the vertical lines to the far left of the photograph. The saw cut would be made at the edge of this image. The last three or four rows are tapered inward, and the serial register is wrapped around vertically so the output amplifier does not increase the width of the device (photograph courtesy of Dr Barry Burke, MIT Lincoln Laboratory).

At one time, drift scanning may have offered some practical advantages such as continuous readout with no dead time, and improved flat fielding in one dimension (the pixel-to-pixel sensitivity non-uniformities in a column are effectively smoothed out by clocking the scene along a column). However, except for specialized projects like the SDSS, these advantages no longer exist. Modern mosaics can be read out quickly (under 1 min), so the readout time is only a small fraction of the typical integration time. Also, modern CCDs do not have the gross flat-field non-uniformities that plagued earlier devices, so the column smoothing obtained by drift scanning is not only unnecessary but viewed as a disadvantage. Furthermore, requiring a telescope and camera to operate in drift scanning mode places strict tolerances on the optical system field distortion because the image tracks cannot deviate from straight lines that must map onto device columns or else the image quality will deteriorate. Considering the advantages and limitations of both methods, the large majority of mosaic cameras have been designed to operate in the shift and stare mode.

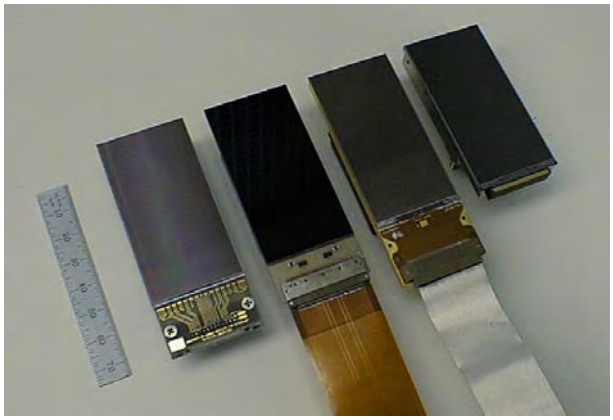

Figure 3. Shown are four 2K×4K three-edge-buttable CCDs with 15 μm pixels from four different manufacturers. These devices are the present-day building blocks for large, close-packed mosaics. From left to right are devices made by Loral (now Lockheed-Martin), MIT Lincoln Laboratory, SITe and EEV. Note that the EEV package has considerably less structure along the wire-bonding edge making it the preferred design for focal planes with more than two rows of devices.

Close-packed CCD mosaic focal planes

For most applications, a continuous focal plane with minimal gaps between the CCD imagers is preferred. While it is not possible to construct a mosaic with zero gaps, there are techniques in the CCD design and packaging that allow for the construction of close-packed mosaics where the gaps are of order 0.5 mm or less.

Device design considerations for close-packed mosaics

To enable CCD imagers to be used in close-packed mosaics, the devices must be specially designed from the outset to be edge buttable. This involves confining the wire bonding pads to only two or, better yet, one of the four edges of the device. Consider a three-edge buttable design. The only structures that need to run up the sides of the device are the metal clock bus lines that distribute the parallel clock signals to the polysilicon gates that establish the potential wells in the imaging region of the device. To keep the dead regions along sides of the device as small as possible, the output amplifier must be designed so it does not not protrude from the side of the device. This can be accomplished by turning a corner with the serial register and tucking the amplifier inside the edge boundary defined by the outermost clock lines (see the photomicrograph in figure 2). Allowing the smallest reasonable space for the vertical bus lines and the boundary to the saw cut, the minimum gap from the imaging area to imaging area on two adjacent arrays is $\sim$200 μm.

Currently, at least three manufacturers (EEV, SITe and MIT Lincoln Laboratory) are producing thinned, high-QE 2K×4K devices with pixels of sizes in the 10–15 μm range that are three-edge buttable and suitable for building large mosaic focal planes (see figure 3).

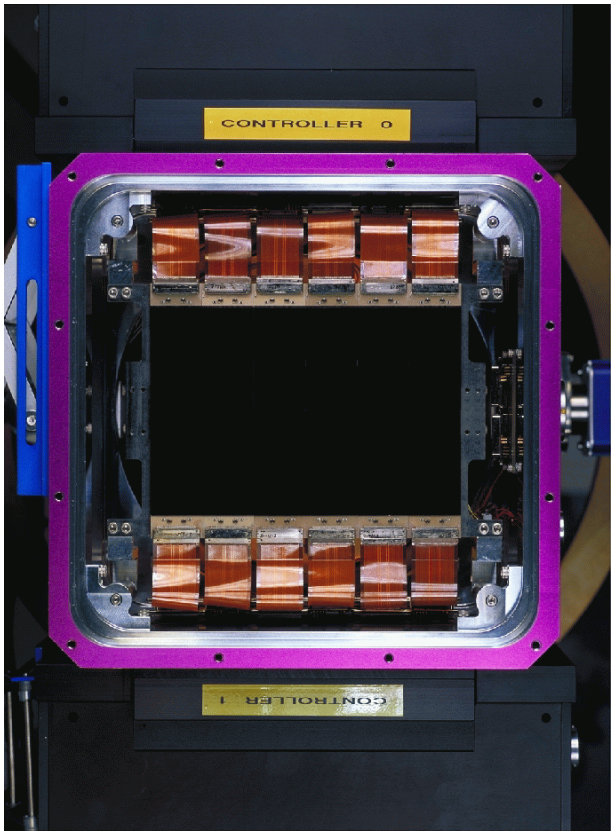

Figure 4. This 8K×12K pixel CCD mosaic camera built by the University of Hawaii for the 3.6 m Canada–France–Hawaii Telescope is the largest close-packed mosaic in operation at the time of this writing (larger mosaic focal planes are under construction). The mosaic consists of 12 thinned, high-QE 2K×4K three-edge buttable CCDs with 15 μm pixels. The devices were made by MIT Lincoln Laboratory. The imaging area, corresponding to the black rectangular region in the center of the photograph, measures 185 mm×122 mm. When used at the prime focus of the CFHT, the mosaic spans a field of view of $45' \times 30'$ at a scale of $0''.21$/pixel. The gaps separating CCDs are less than 0.5 mm or less than $10''$ on the sky.

Packaging and mosaic construction

Once an edge-buttable device is designed, it can be mounted close to its neighbors to form a CCD mosaic. The very first attempts at this involved permanently attaching (i.e. gluing) the CCD dies to a common substrate. There are several disadvantages to this approach. A mosaic assembled in this manner cannot be taken apart safely if one of the CCDs is damaged. Furthermore, the selection of the CCDs that will be used in a mosaic involves thorough testing at cryogenic temperatures. This is difficult to accomplish with unpackaged CCD dies, so one could permanently assemble a mosaic and find after it is completed and tested that some of the mosaic elements are not suitable for scientific observations. These problems led to the development of edge-buttable packages that do not compromise the tight packing ability of the buttable imagers and yet allow a mosaic focal plane to be assembled and dis-assembled. Examples of such packages are shown in figures 3 and 4. In choosing a package material, one must consider that the device will be operated at ∼170 K, so the coefficient of thermal expansion difference between that material and silicon is important. The standard package materials that are a reasonable thermal expansion match to silicon are aluminum nitride (AlN), Invar and molybdenum.

Using the devices shown in figure 3, several close-packed CCD mosaic focal planes containing at least 8K×8K pixels have been constructed and are in operation (e.g. UH 8K×8K, NOAO 8K×8K mosaic imagers for the Kitt Peak and CTIO 4m telescopes, ESO 8K×8K, CFHT 8K×12K—see figure 4).

Devices that are three-edge buttable are suitable for close-packed mosaics having two rows and an unlimited number of columns. If one wants to build a larger mosaic with more than two rows, one must tolerate a larger gap between the rows on the fourth, non-buttable edge. With these larger mosaics in mind, some designs have been developed for pseudo four-edge buttable packages that minimize the packaging structures along this fourth edge. EEV has developed a package (see figure 3) that keeps the dead space along this fourth edge to under 3 mm from the edge of the bottom imaging row to the edge of the package. Another prototype design with a 3 mm dead space is shown in figure 5.

The future

Widefield CCD imagers are at present being constructed by many observatories. Several current projects are designed to span fields in excess of $1^\circ \times 1^\circ$ using CCD mosaics measuring 18K×18K pixels. If widefield imaging telescopes with $3^\circ \times 3^\circ$ fields are constructed, they will require CCD mosaics having 36K×36K pixels or more. Work is also progressing on the designs for the individual building blocks that make up the mosaic elements. Three-edge buttable devices with 3K×6K 10 μm pixels are now under development, and wafer-scale devices that can fill a 150 mm wafer are being considered as yields improve.

On-chip image motion compensation—the OTCCD

One exciting CCD variation that has emerged in recent years is the multi-directional or orthogonal-transfer CCD (OTCCD)—a device that can shift charge in up to eight directions, thus allowing active image motion compensation or fast guiding 'on chip' (see figure 6). A mosaic array of close-packed, independently addressable OTCCDs would allow compensation for image motion caused by the atmosphere over very wide fields, as well as correcting for windshake and other mechanical pointing instabilities common to the telescope as a whole.

Large, buttable OTCCDs with 2K×4K pixels have been successfully fabricated and the first mosaics of such devices are at present under construction. Even larger devices subdivided into small ($\sim 1' \times 1'$) independently controllable OTCCD cells are under development.

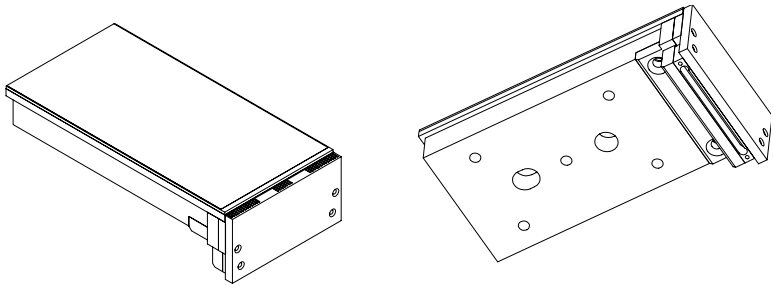

Figure 5. This drawing shows one design for a package that can be used in close-packed mosaics having more than two rows. A ceramic piece with metallized traces that wrap around one edge is mounted at right-angles to the device. Wire bonds are made to the traces on the short edge of the ceramic and the traces connect the signals to a surface mount connector that emerges from the backside of the package. Mounting holes and alignment holes are shown for locating the package in focal plane mosaic.

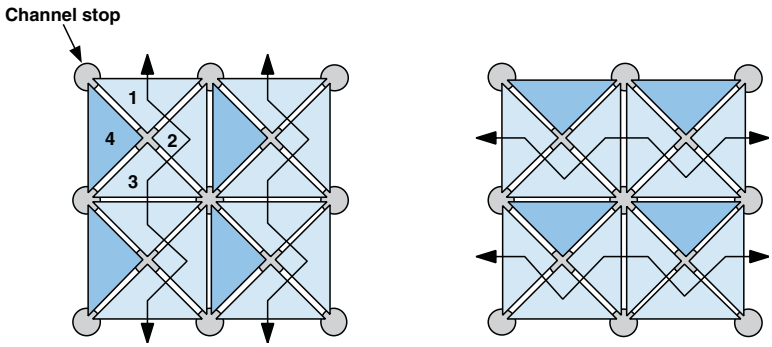

Figure 6. This diagram illustrates the gate layout and charge clocking directions for a multi-directional OTCCD. The symmetry of the gate structure allows clocking of the charge in eight directions: horizontally and vertically (as shown), or diagonally. Subpixel stepping is also possible. In this image, the triangular structures are polysilicon gates that can be biased to form the potential wells in the silicon below. This type of structure requires four gates per pixel, whereas the typical CCD has only three gates. In the illustration at the left, the dark triangular gate is biased low to serve as a barrier phase while the other three phases are modulated to transfer the charge in the vertical direction. At the right, a different gate serves as the barrier phase, and, by modulating the voltage on three different gates, the charge can be transferred in the horizontal direction.

Bright stars and antiblooming

Bright stars present a serious problem for widefield CCD imaging. Even at high GALACTIC LATITUDE, there are numerous bright ($m < 15$) and several very bright ($m < 10$) stars in any $0^\circ.5 \times 0^\circ.5$ field. Larger fields only make the problem worse. Light from these stars can reflect off optical surfaces, including the surface of the CCD itself, and create out-of-focus halos and other scattered light artifacts. Large diffraction spikes can extend well away from the bright stars and break up into faint pieces, resembling faint galaxies, especially in very good seeing. Bright stars will also produce saturated, bloomed charge trails; the result of filling the pixel potential well capacity (typically 150 000–300 000 e^-) and having the excess charge spill up and down the columns into the neighboring pixels. For some brighter stars, the bloomed trails can extend the full length of the device, destroying any information about objects in the path of the bloomed trail. Device manufacturers can address the blooming problem by implementing antiblooming drains in their CCD structures. An antiblooming drain is an implant on the CCD with a potential level near full well, but slightly less than the barrier potential of the neighboring vertical phases. When the charge in a pixel exceeds the potential level of the drain, but before the charge can spill over to the neighboring pixel, it is intercepted by the drain. Such structures can be made so that they do not obscure any of the imaging regions (e.g. the drain can be run down the center of the channel stop). Implementation of such structures will be very valuable in future devices designed for widefield imaging.

Widmanstätten Pattern

A characteristic, roughly hexagonal pattern of intersecting lines that appears on the surface of an octahedrite, a type of iron meteorite, when it is sectioned, polished and etched with acid. The Austrian mineralogist Aloys Joseph von Widmanstätten discovered the pattern in 1804. It is formed by the intergrowth of two nickel–iron alloys under the conditions of slow cooling that pertained in the solidifying core of an asteroidal parent body that had undergone differentiation, and is found only in meteorites. The two alloys are kamacite, with a low nickel content, and taenite, which is richer in nickel.

Wilcox Solar Observatory

The Wilcox Solar Observatory (WSO) at Stanford University measures the Sun's large-scale synoptic magnetic and velocity fields with the goal of understanding solar variability and how it affects our terrestrial environment. With more than a 22 year solar cycle of spectrograph observations since 1975, WSO staff investigate the solar interior, photosphere, corona, wind and cycle.

The Observatory was first funded by the Office of Naval Research (ONR), the National Science Foundation (NSF) and the M C Fleischman Foundation. Continuing support comes from NSF, NASA and ONR. The Observatory was rededicated in honor of its first director, J M Wilcox, in 1984, shortly after his death. Stanford University is located south of San Francisco, CA.

WIMPs and MACHOs

WIMP is an acronym for weakly interacting massive particle and MACHO is an acronym for massive (astrophysical) compact halo object. WIMPs and MACHOs are two of the most popular DARK MATTER candidates. They represent two very different but reasonable possibilities of what the dominant component of the universe may be.

It is well established that somewhere between 90% and 99% of the material in the universe is in some as yet undiscovered form. This material is the gravitational glue that holds together galaxies and clusters of galaxies and plays an important role in the history and fate of the universe. Yet this material has not been directly detected. Since extensive searches have been done, this means that this mysterious material must not emit or absorb appreciable electromagnetic radiation in any known waveband. Thus it is called dark matter. The nature of this material is one of the biggest unsolved problems in science. It is important to identify the dark matter, but since it is easy to invent substances that could fill intergalactic space and yet have escaped detection, there are a very large number of dark matter candidates. Thus several generic classes of dark matter candidates have been suggested, and each dark matter search experiment concentrates on one of these classes. The most important dark matter classes, in terms of detection efforts, are neutrinos, WIMPs, MACHOs and axions.

For example, NEUTRINOS are weakly interacting particles that were almost certainly created in great abundance during the big bang. These fill the Galaxy, moving freely through the Galaxy and even the Earth, and yet are almost impossible to detect. This is because they can be sensed only through the very small electroweak interaction. If each neutrino had a mass of several electronvolts they would contribute enough mass to make up the bulk of the dark matter. For various reasons, it is unlikely that neutrinos of the type discovered in particle accelerators and nuclear reactors on Earth make up much of the dark matter.

However, it is very possible that some as yet undiscovered weakly interacting particle was created during the big bang and today remains in large enough abundance to make the dark matter. The masses typically required for these particles are in the range 1 GeV–1 TeV, and these hypothetical dark matter particles are called WIMPs. There are hundreds of elementary particles that fall into this class of dark matter particles, including supersymmetric particles such as neutralinos, photinos, higgsinos or sneutrinos, and new heavy neutrinos.

This hypothetical WIMP is well studied and attempts to detect these particles have been mounted both by creating them in accelerators and by sensing them in underground detectors as they pass through the Earth. However, there is a large class of astronomical objects that could be the dark matter and still escape detection. For example, if the Galactic halo were filled with Jupiter mass objects ($10^{-3}M_{\dot{o}}$) they would not have been detected by emission or absorption of light. Brown dwarf stars with masses below $0.08M_{\dot{o}}$ or the black hole remnants of an early generation of stars would be similarly invisible. Thus these objects are examples of MACHOs. Other examples of this class of dark matter candidates include primordial black holes created during the big bang, neutron stars, white dwarf stars and various exotic stable configurations of quantum fields, such as non-topological solitons.

An important difference between WIMPs and MACHOs is that WIMPs are non-baryonic and MACHOS are typically (but not always) formed from baryonic material. As discussed in the article on big bang nucleosynthesis (see UNIVERSE: THERMAL HISTORY), baryonic material probably cannot make up all of the dark matter, although it could make up most of the dark matter in the halos of spiral galaxies such as the Milky Way. There is preliminary, although controversial, evidence for the existence of large numbers of MACHOs, but because they probably cannot make up all the dark matter, the search for WIMPs continues unabated.

WIMP thermal relics as dark matter

Among the particle dark matter candidates an important distinction is whether the particles were created thermally in the early universe, or whether they were created non-thermally in a phase transition. Thermal and non-thermal relics have a different relationship between their relic abundance Ω and their properties such as mass and couplings, so the distinction is especially important for dark matter detection efforts. For example, the WIMP class of particles can be defined as those particles that are created thermally, while dark matter axions come mostly from non-thermal processes. Light neutrinos are also thermally created relics, but because of their very small mass have a different history.

In thermal creation one supposes that early on, when the universe was at very high temperature, thermal equilibrium obtained, and the number density of WIMPs (or any other particle species) was roughly equal to the number density of photons (particles of light)[1]. This is just equipartition of energy among all possible degrees of freedom. As the universe cooled the number density of WIMPs and photons decreased together. When the temperature finally dropped below the WIMP mass, however, creation of WIMPs became very rare while annihilation still proceeded. Thus in equilibrium, the number density of WIMPs dropped exponentially : $\exp(-m_{WIMP}/T)$. If equilibrium were maintained until

[1] There is a small difference between the number density of photons and neutrinos since photons obey Bose–Einstein statistics and neutrinos obey Fermi–Dirac statistics.

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

today there would therefore be very few WIMPs left, but at some point the WIMP density dropped low enough that the probability of one WIMP finding another to annihilate became small. Note, we must assume that an individual WIMP is stable if it is to become the dark matter. The WIMP number density stopped dropping at this point and we are left with a substantial number of WIMPs today. Detailed evolution of the Boltzmann equation that describes this process can be done for an accurate prediction, but roughly the predicted relic density today of WIMPs is inversely proportional to their interaction strength. The remarkable fact is that, for a relic density equal to the known dark matter density, the interaction strength must be that expected for particles with electroweak-scale interactions: thus the 'W' for 'weakly' in 'WIMP'. There are several theoretical problems with the standard model of particle physics that are solved by new electroweak-scale physics such as SUPERSYMMETRY. Thus these theoretical problems may be clues that the dark matter does indeed consist of WIMPs. Said another way, any stable particle that annihilates with an electroweak-scale cross section is bound to contribute to the dark matter of the universe. It is interesting that theories such as supersymmetry, invented for entirely different reasons, typically predict just such a particle.

The fact that thermally created dark matter has weak-scale interactions also means that it may be within reach of accelerator experiments such as LEP and LHC at CERN, and the proton collider experiments at Fermilab. Thus many accelerator searches for exotic particles are also searches for the dark matter of the universe. Also, because of the weak-scale interactions, WIMP–nuclear interaction rates are within reach of many direct and indirect detection methods, as discussed below.

Supersymmetry and dark matter

Supersymmetry is a new hypothetical symmetry of nature that relates bosons and fermions. If supersymmetry exists in nature then every known particle should have a supersymmetric partner. Bosonic ordinary particles have fermonic superpartners with the same name except with the suffix 'ino' added, while fermonic ordinary particles have bosonic (scalar) superpartner names with the prefix 's' added. Examples of proposed supersymmetric particles include photinos, higgsinos, Z-inos, squarks and selectrons. Some supersymmetric particles have the same quantum numbers as each other and therefore can mix together producing particles that are not exact partners of any standard model particle. For example, the photino, Higgsino and Z-ino can mix into arbitrary combinations called the neutralinos.

In most models, the lightest supersymmetric particle (LSP) is stable, and since supersymmetric particles have electroweak-strength interactions, the LSP makes an excellent dark matter candidate. Typically the neutralino is the LSP so most investigations of WIMP dark matter have concentrated on the neutralino. However, there are many possible supersymmetric models and many free parameters in the models, so precise predictions of supersymmetric relic abundance and supersymmetric particle detectability are not possible. Typically experiments attempt to probe a range of model parameters. So far no concrete evidence of any supersymmetric partner exists. If even one supersymmetric partner is found, the theory predicts that they all must exist.

Note that the parameters that determine the relic abundances also determine all the particle production and rare decay cross sections, as well as the rate in various detectors. Thus once these parameters are specified or measured, one can compare the model predictions with experimental results.

Search for WIMPs

Accelerator searches

Extensive unsuccessful searches for the particles involved in supersymmetric models have been performed at particle accelerators throughout the world. Thus substantial regions of prime neutralino dark matter parameter space have already been eliminated. This does not yet mean that low-energy supersymmetry is unlikely to exist, since only a small portion of the allowed mass range under 1 TeV has been explored. Since supersymmetry predicts a Higgs boson with mass under about 120 GeV, such a discovery would be very important, especially if the Higgs boson showed non-standard properties indicative of supersymmetry. It is correct to think of the particle physics search for supersymmetry as a powerful search for the dark matter.

Direct detection of WIMPs

A satisfying solution to the dark matter problem would be the detection of WIMPs from our Galactic halo as they move past and through the Earth. This would also allow measurement of the local density of dark matter and establish beyond doubt that the dark matter is non-baryonic cold dark matter. There are several ways to do this, and currently two methods are being aggressively pursued.

The most exciting result would be direct detection of the WIMP particles in the laboratory. Since we roughly know the speed (~220 km s^{-1}) and the density (ρ~0.3 proton masses cm^{-3}), we can say that for a WIMP of mass of order 10–100 GeV, roughly 100 000 dark matter particles per second pass through every square centimeter of the Earth. However, if WIMPs exist, they are very weakly interacting particles, so it is quite rare that one of them will interact at all; most of them pass right through the Earth unimpeded. In addition, if a WIMP does elastically scatter off a nucleus, the deposited energy is usually in the keV to 100 keV range, too small to be noticed

Copyright © Nature Publishing Group 2002

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

except by exquisitely sensitive equipment. These difficulties, however, have not stopped many groups throughout the world from developing devices capable of detecting WIMPs. The detection rates turn out to be within and just beyond the reach of current experimental efforts.

The basic idea is to detect the small energy deposited when a WIMP scatters off a nucleus in some well-instrumented piece of material. When a WIMP scatters off a nucleus in a crystal, the nucleus recoils, causing dislocation in the crystal structure, vibrations of the crystal lattice (i.e. phonons or heat) and also ionization. These signals can be detected. For example, some experiments use kilogram size germanium and silicon crystals and attempt to detect the ionization and phonon signals. Other groups use sodium iodide crystals and look for the scintillation light caused by the ionized electrons or search for crystal dislocations in samples of billion year old mica. Another possibility is to record the recoil of an ionized atom in a gas using drift chamber techniques.

The main difficulties in these experiments come from the fact that the WIMP events are rare and that there are many backgrounds that deposit similar amounts of energy on much more frequent time-scales. Thus the experiments operate deep underground, where ionizing COSMIC RAYS are less frequent, and typically operate their detectors at extremely cold temperatures to keep thermal excitations low. Also many types of shielding, as well as redundant detection methods, are now becoming standard. Even so, these are difficult experiments and tiny amounts of radioactivity in the detector or shielding can swamp the expected signal. With effort, a background rate of under one event per kilogram of detector per day can be achieved. The expected signal is highly dependent on the supersymmetry model, but typically is in the range from 10^{-5}–10 events kg^{-1} day^{-1}. The events can be separated from the background in two ways. In some detectors the background (non-WIMP) interactions can be recognized and simply ignored. In the larger detectors this is not possible, so they use the fact that the WIMP event rate is predicted to be larger in June than in December. This annual modulation in event rate is caused by the Earth's orbit either being aligned with the Sun's motion in the Galaxy (in June) or anti-aligned (in December).

The current generation of detectors have detection thresholds of around 1 event kg^{-1} day^{-1}, with hopes that within the next few years signals as small as 10^2 events kg^{-1} day^{-1} will be detectable. Thus there is a reasonable chance that dark matter neutralinos will be detected by this type of direct detection within the next few years. It is also clear, however, that there are many values of the supersymmetry parameters that predict detection rates of below the 10^{-2} events kg^{-1} day^{-1} threshold, and so would not be detectable in the near future by these methods.

Indirect detection of WIMPs

A great deal of theoretical and experimental effort has gone into another potential technique for WIMP detection. The idea is that if the halo is made of WIMPs, then these WIMPs will have been passing through the Earth and Sun for several billion years. Since WIMPs will occasionally elastically scatter off nuclei in the Sun or Earth, they will occasionally lose enough energy, or change their direction of motion enough, to become gravitationally captured by the Sun or Earth. The orbits of such captured WIMPs will repeatedly intersect the Sun (or Earth) resulting in the eventual settling of the WIMPs into the core. As the number density increases over time, the self-annihilation rate will increase. Since ordinary neutrinos can result from WIMP self-annihilation, one predicts a stream of neutrinos coming from the core of the Sun or Earth. Neutrinos easily escape the Solar core and detectors on Earth capable of detecting neutrinos coming from Sun or Earth have operated for some time. The energy of such neutrinos is roughly 1/2 to 1/3 of the WIMP mass, so these neutrinos are much higher energy than the MeV scale solar neutrinos from nuclear reactions that have already been detected. The higher energy of these WIMP annihilation neutrinos makes them easier to detect than ordinary solar neutrinos and somewhat compensates for their much fewer numbers. It also makes them impossible to confuse with ordinary solar neutrinos. Thus the presence of a source of high-energy neutrinos emanating from the centers of the Sun and Earth would be taken as evidence for WIMP dark matter.

While the above chain of reasoning may seem long, it appears to be robust, and several experimental groups are in the process of designing and building detectors capable of seeing such a neutrino signal. For this signal, it is not the mass of the detector that is relevant, but the surface area. Neutrinos from the core of the Sun or Earth produce muons in the atmosphere and rock around the detectors, and it is primarily these muons that the detectors watch for. Muons are also copiously created by cosmic rays entering the Earth's atmosphere, so there is a substantial background of 'downward' traveling muons. These detectors, then, are located deep underground, where the rock shields many of the background muons, and they also focus on 'upward' traveling muons, that are much more likely to have been created by neutrinos that have traveled through Earth and interacted in the rock just below the detector. Thus surprisingly, the best way to see high-energy neutrinos from the Sun is to go deep underground at night (when the Sun is 'under' the Earth).

The new generation of detectors are designed to have very large surface areas. A comparison of direct and indirect detection methods indicates that for a typical neutralino a kilogram of direct detector germanium has about the same sensitivity as 10^4–10^6 m^2 of indirect

Dirac House, Temple Back, Bristol, BS21 6BE, UK

detector. The new generation of detectors should have areas in this range and should be able to start to probe realistic supersymmetry models, but again viable supersymmetric models exist which predict rates too small for these detectors to measure, and a definitive test of the WIMP hypothesis does not seem possible in the near future.

MACHOs and microlensing

An exciting development in the dark matter story is the detection of MACHOs by three separate groups, MACHO, EROS and OGLE. All three groups monitored millions of stars in the LARGE MAGELLANIC CLOUD (LMC), in the SMALL MAGELLANIC CLOUD (SMC) or in the GALACTIC BULGE, for signs of gravitational microlensing, and all three groups have found it. It has now become clear that these objects constitute some new component of the Milky Way, but whether they constitute a substantial part of the dark matter or new stellar components of the Galaxy or LMC is not clear.

MICROLENSING is a powerful new tool for discovering and characterizing populations of dark objects in our Galaxy, and the current experiments may have the capability to give a definitive answer to the question of whether the dark matter in our Galaxy is baryonic. The reason is that the microlensing searches are probably sensitive to any objects in the range $10^{-8}M_{\odot}<m<10^{3}M_{\odot}$, just the range in which such objects are theoretically allowed to exist. Objects made purely of H and He with masses less than ~(10^{-9}–$10^{-7}M_{\odot}$) are expected to evaporate owing to the microwave background in less than present age of the universe, while dark matter objects with masses greater than ~$10^{3}M_{\odot}$ would have disrupted known GLOBULAR CLUSTERS. So unlike the searches for WIMP dark matter, which if they detect nothing will remain inconclusive, if the MACHO searches find nothing, we would at least know what the dark matter is not. However, the MACHO searches have found something, as we describe below.

Microlensing is also described in the article on GRAVITATIONAL LENSING. The idea of microlensing rests on Einstein's observation that, if a massive object lies directly on the line of sight to a much more distant star, the light from the star will be lensed and form a ring around the lens. The ring is called the 'Einstein ring' and it sets the scale for all the microlensing searches. In the lens plane, the radius of the ring is given by

$$r_E = 610R_{\odot}\left(\frac{m}{M_{\odot}}\frac{L}{\mathrm{kpc}}x(1-x)\right)^{1/2}$$

where $R_{\odot}$ and $M_{\odot}$ are the solar radius and mass, m is the MACHO mass, L is the distance to the star being monitored and x is the distance to the MACHO divided by L. The formation of a ring is very unlikely, but even with imperfect alignment two images result and a large magnification can occur.

Since the MACHO, Earth and source star are all in relative motion, the star appears to brighten, reaches a peak brightness, and then fades back to its usual magnitude. Thus the signature for a microlensing event is a time-symmetric brightening of a star occurring as a MACHO passes close to the line of sight. When a microlensing event is detected, one fits the lightcurve and extracts the peak magnification A_{max}, the time of the peak, t_0, and event duration $\hat{t}$. The primary physical information comes from $\hat{t}$, which depends on the MACHO velocity, the MACHO mass, the source distance, and the lens distance. The source distance can be determined since it is visible, but unfortunately, one cannot determine the other three physical parameters from $\hat{t}$. However, statistically, one can use information about the halo density and velocity distribution, along with the distribution of measured event durations to gain information about the MACHO masses. Using a standard model of the dark halo, MACHOs of Jupiter mass ($10^{-3}M_{\odot}$) typically cause events lasting 3 days, while brown dwarf mass MACHOs ($0.1M_{\odot}$) cause events lasting about a month.

Assuming a halo made entirely of MACHOs, the probability of any MACHO crossing in front of a star is about 5×10^{-7}. Thus many millions of stars must be monitored in order to see a handful of microlensing events. In addition, if one wants to see microlensing from objects in the dark halo, the monitored stars must be far enough away so that there is a lot of halo material between us and the stars. Therefore, the best stars to monitor are those in the LMC and SMC at distances of 50 kpc and 60 kpc respectively, stars in the galactic bulge at 8 kpc and stars in nearby galaxies such as M31 at 750 kpc.

Microlensing experiments

There are several experimental groups that have undertaken the search for microlensing and have returned results. All together about a dozen events have been detected towards the LMC, a couple towards the SMC, and more than 400 towards the galactic bulge. For detection of dark matter MACHOs, it is primarily the LMC events that are relevant. All survey collaborations operate a medium-size telescope and monitor millions of stars nightly. Since the fields are crowded, each CCD frame contains hundreds of thousands of stellar images, the brightness of each which must be determined by computerized photometry. These stellar brightnesses are arranged sequentially in a lightcurve, each of which is finally searched for microlensing-like bumps. All together many terabytes of data have been analyzed by the survey experiments.

Most of the monitored stars are constant brightness as one expects, but about one-half of 1% are variable.

and Institute of Physics Publishing 2002
Dirac House, Temple Back, Bristol, BS21 6BE, UK

These are mostly identified as variable stars of known types. Several signatures of microlensing, including the unique shape of a microlensing lightcurve are used to pick out microlensing events from this background of variable stars. For example, the MACHO collaboration analyzed about 9.5 million lightcurves from its 2 yr LMC data set and found six to eight microlensing events.

Experimental results

In order to interpret microlensing events, the efficiency with which an experiment can detect microlensing is needed. Bad weather, bad seeing, crowded stars, etc cause microlensing events to be missed by the experiment. The MACHO collaboration finds an efficiency of around 30% for microlensing events that last 50 days. For events lasting less than a few days and events lasting longer than 6 months the efficiency is very low.

Using the efficiency and a model of the dark halo, the number of microlensing events one expects to see if the halo consisted entirely of MACHOs is found to be about a dozen for the MACHO collaboration 2 yr data set. This quantity is related to the lensing 'optical depth', the roughly 5×10^{-7} probability that at any time a source star is lensed (if the halo is made entirely of MACHOs).

Using the eight observed MACHO collaboration LMC events, the observed optical depth is $\sim(2.5\pm1\times10^{-7})$, roughly half the value if the halo consisted entirely of MACHOs. A careful likelihood analysis of these events gives, for a standard dark halo model, a most likely MACHO halo fraction of 0.5±0.3 and a most likely mass of the MACHOs of around $0.5M_{\odot}$. This result depends on the assumption that the events are due to lenses in the Galactic halo and on the model of the galactic halo used.

Another analysis based on noticing that none of the eight detected events had durations of less than 20 days can rule out low-mass MACHOs. This is because $\hat{t}: m^{1/2}$, and no short-duration events have been observed toward the LMC. This analysis gives the strongest constraints to date on the baryonic content of the dark halo. The EROS and MACHO collaboration limits show that objects in the mass range from $10^{-7}M_{\odot}$ to $10^{-3}M_{\odot}$ cannot make up the entire dark halo. Objects in the range from 3.5–$10^{-7}M_{\odot}$ to 4.5–$10^{-5}M_{\odot}$ make up less than 10% of the dark halo. Thus we now know that the dark matter is not mostly objects of Earth mass, or Jupiter mass, or any combination thereof. The only compact baryonic dark matter candidates left are objects in the brown dwarf and higher mass range. This result is independent of any assumptions about the observed microlensing events, but does depend on the model of the dark halo.

In 2002, an international team of astronomers observed a dark matter object directly for the first time. Images and spectra of a MACHO microlens were taken by the NASA/ESA HUBBLE SPACE TELESCOPE (HST) and the European Southern Observatory's Very Large Telescope (VLT). This result is a strong confirmation that gravitational microlensing is the cause of the events detected by teams searching for MACHO dark matter.

In addition, Christopher Kochanek of the Harvard–Smithsonian Centre for Astrophysics in Cambridge, Massachusetts and Neal Dalal of the University of California, San Diego have used radio telescopes and gravitational lensing to search for cold dark matter. They have studied seven galaxies, each magnified by four nearer ones. Because each lensing galaxy is in a slightly different position, the researchers got four different images of each of the seven distant galaxies. The four images should have been identical. But each is actually slightly different. The difference was enough to have been caused by the kind of clumps of dark matter around lensing galaxies that mathematical models predict.

Interpretation of results: dark matter or not?

The naive interpretation of the microlensing results is that between 20% and 80% of the dark matter in the Milky Way has been identified. However, the result that the mass of the objects is above the brown dwarf limit of $0.1M_{\odot}$ is surprising. Main sequence stars with masses above $0.1M_{\odot}$ would have been seen and therefore cannot be the dark matter. Several interpretations are possible.

First, perhaps the MACHOs are white dwarf stars or neutron stars. These are dark remnants of an earlier generation of stars, but it is problematic to have enough of these around to be the dark matter and not have detected the other byproducts of such an early stellar population. Second, perhaps the model of the Galactic halo used is incorrect, and the masses of the MACHOs are actually safely below the brown dwarf limit. However, most reasonable halo models investigated do not have this property. Next, perhaps MACHOs are primordial black holes, or other exotic objects not currently known. This is possible, but quite surprising. Most importantly, perhaps the microlensing events are not due to halo lenses, and therefore are not telling us about the dark matter. In a typical microlensing event, the distance of the MACHO is not determined, so it is not known where the lens population is located. The estimate of the amount of MACHO dark matter relies on an assumed distribution of lens material, and therefore on the model of the Galaxy and LMC.

It has been suggested that the lenses could be faint stars in the LMC itself, or in some small undiscovered dwarf galaxy between the Sun and the LMC. These possibilities are being vigorously pursued, but strong arguments have been given against both possibilities. Thus the outcome is very unclear at the moment.

If one could measure the distance to the MACHO, that would be enough to distinguish between the above possibilities. Thus a 'microlensing parallax' satellite has been proposed to measure these distances. Other ways to

measure the distance to lenses, and therefore determine whether or not they are part of the dark halo, include ground-based lensing parallax, binary lens caustic crossing, and the finite source star effect. Unfortunately, events where these effects can be measured are rare, so luck, or new larger surveys and better follow-up, is needed to resolve this issue of what the MACHOs are.

The next generation of microlensing surveys and follow-up efforts are underway or being planned and should determine some lens distances, as well as gather more events. Thus, while the question of baryonic dark matter remains open, the next few years should bring an answer.

Wind

NASA satellite, part of NASA's Global Geospace Science programme and the International Solar Terrestrial Physics programme. Launched November 1994. For the first nine months it followed a double-lunar swingby orbit with apogee of 80–250 Earth radii and perigee 5–10 Earth radii. In this orbit, lunar gravity assists maintained apogee over Earth's day hemisphere for magnetospheric observations. Later inserted into a 'halo' orbit at the sunward Sun–Earth gravitational equilibrium point (L1) to measure the solar wind, magnetic fields and particles, and provide a one-hour warning to other ISTP spacecraft of changes in the solar wind. Since October 1998, placed in 'petal' orbits that take it out of the ecliptic plane.

Wise Observatory

Wise Observatory, in Mitzpe Ramon, Israel, is owned and operated by Tel Aviv University, and has a well-equipped 1 m telescope. Since construction in 1971, the large percentage of clear nights at its desert site and its unique longitude have made the observatory particularly useful for long-term monitoring projects (e.g. reverberation mapping of quasars and active galaxies), and as a part of global monitoring networks (e.g. the first detection, via gravitational microlensing, of a planet orbiting a binary star system).

Wittich, Paul (*c*. 1546–86)

Born in Breslau, Silesia (now Wroclaw, Poland), invented (or at least developed) 'prosthaphaeresis', a formalism of trigonometry that allowed one to multiply and divide trigonometric functions by the easier process of adding and subtracting instead (in the manner of logarithms). He wrote a commentary on COPERNICUS'S *De Revolutionibus*, which foreshadowed the Tychonic system. He worked with TYCHO BRAHE for four months at Uraniborg.

WIYN Observatory

Located at Kitt Peak in Arizona. The WIYN Observatory is owned and operated by the WIYN Consortium, which consists of the University of Wisconsin, Indiana University, Yale University and the National Optical Astronomy Observatories (NOAO). Most of the capital costs of the observatory were provided by these universities, while NOAO, which operates the other telescopes of the KITT PEAK NATIONAL OBSERVATORY, provides most of the operating services.

The 3.5 m WIYN Telescope, which was completed in 1994, is the second largest telescope on Kitt Peak. The size of the telescope enclosure is kept to a minimum by the short focal length of the primary mirror, which results in a shorter telescope, while the alt-azimuth mount requires less space. The moving weight of the telescope is a mere 46 tons.

Other innovative design features are active primary mirror supports, primary mirror thermal controls and active ventilation of the telescope mount. The support system for the primary mirror includes 66 actuators, which adjust the back face of the mirror to maintain the best optical figure. The primary mirror thermal control system keeps the temperature of the mirror's surface to within 0.2 °C of the ambient air temperature, eliminating local turbulence. These innovations enable the WIYN Telescope to produce much sharper images than any of the other telescopes on Kitt Peak.

WIYN is equipped with the latest instruments for astronomical spectroscopy and imaging. A multiple-object spectrograph employing optical fibers allows the simultaneous observation of the spectra of 100 objects. The imaging cameras employ highly sensitive arrays of electronic detectors.

Wolf, Charles J E (1827–1918)

French astronomers Charles Wolf and GEORGES RAYET, using the 40 cm Foucault telescope of the Paris Observatory, visually observed the spectra in 1867 of several eighth magnitude stars in Cygnus before the systematic use of photographic plates and found very broad emission lines. The 'bands' were originally thought to be hydrocarbon molecules. The stars became known as *Wolf–Rayet (WR) stars*.

Wolf, Johann Rudolf (1816–93)

Born in Fällanden (near Zurich), Switzerland, became professor of astronomy at the University of Bern and director of the Bern Observatory, then professor of astronomy in Zürich where he founded an observatory. He devised a system now known as *Wolf's sunspot numbers* used to quantify solar activity by counting sunspots and sunspot groups and used it to confirm the sunspot cycle discovered by HEINRICH SCHWABE and measure its period at 11 years. He also co-discovered with EDWARD SABINE its connection with geomagnetic activity.

Wolf, Max[imilian] Franz Joseph Cornelius (1863–1932)

Astronomer, born in Heidelberg, Germany, founded and became first director of the Königstuhl Observatory at the University of Heidelberg. He took wide-field photographs of the Milky Way and counted stars of different brightnesses, plotting the results in a *Wolf diagram* of number versus magnitude to prove the existence of clouds of obscuring dust. He showed that the spiral nebulae have absorption spectra typical of stars, rather than emission spectra from gas. He pioneered the use of photography to discover hundreds of asteroids.

Wolf–Rayet Nebula

Nebulosity surrounding a Wolf–Rayet star. Wolf–Rayet stars are of around 10 solar masses and have very high surface temperatures, up to about 40 000 K. This gives them powerful stellar winds, up to 2000 km s^{-1}, and an enormous rate of mass loss. Material is usually ejected in the form of a spherical shell or ring (the term *Wolf–Rayet bubble* is sometimes used), and the accumulating envelope from successive ejection episodes comprises the nebula. Examples of Wolf–Rayet nebulae are NGC 2359, surrounding the star HD 56925, and NGC 6888, surrounding the star MR 102.

Wolf–Rayet Stars

Wolf–Rayet (W–R) stars are a class of peculiar stars first identified in 1867 by C J E WOLF and G RAYET. Unlike the spectra of most stars, which are dominated by narrow absorption lines, the spectra of W–R stars show broad emission lines. The rich emission line spectrum makes them easy to identify, by spectroscopic observations, even at large distances.

W–R stars are divided into three broad spectroscopic classes (WN, WC and WO) based on the emission lines present in their spectrum. WN stars show emission lines predominantly of helium and nitrogen, although emission due to carbon, silicon and hydrogen can readily be seen in some of these objects. In contrast, the spectra of WC stars are dominated by carbon and helium emission lines with hydrogen and nitrogen emission absent (figure 1). WO stars, which are much rarer than either WN or WC stars, are similar to WC stars except that oxygen lines are more prevalent, and there is a tendency to exhibit lines arising from atomic species of higher ionization.

These spectral classes are further divided into subclasses on the basis of line ratios, yielding a classification by ionization. The WN stars which exhibit spectra showing emission from high-ionization species (e.g. He II, N V, O VI)[1] are designated WN2. Those showing emission from low-ionization species (e.g. He I, N III) are classified as WN9, although recently the W–R spectral classification has been extended to WN11. Similarly, WC stars showing emission from high-ionization species (e.g. He II, C IV, O VI) are designated WC4 while those exhibiting the lowest ionization (e.g. He I, C II) are designated WC9. In the literature there is also a tendency to refer to WN stars of classes 2–5 as early type (WNE) and classes 6–9 as late type (WNL). Similarly, WC4–6 stars are designated as WCE, while WC7–9 stars are designated as WCL. Although there are important exceptions, WNE stars generally show no evidence for H emission while H emission is present in WNL stars.

The distribution of population I W–R stars, which are discussed in this article, is similar to that of O stars; they are primarily located in the spiral arms of our galaxy and near H II regions. W–R masses range from an uncertain lower limit of about $5M_{\odot}$ to in excess of $60M_{\odot}$, while surface temperatures range from a lower limit of 25 000 K to greater than 100 000 K. Because of their spatial association with O stars, and their peculiar surface abundances, W–R stars are generally believed to be descended from O stars.

Approximately 220 W–R stars are known in our Galaxy but this number is certainly incomplete. Most are hidden from our view by dust, which absorbs and scatters light (a process termed interstellar extinction) within our Galaxy. Estimates of the total number of W–R stars in our Galaxy range from 1000 to 2000. The rarity of W–R stars is due to the initial mass function, which favors the production of low-mass stars, and the short evolutionary lifetime of W–R stars, which is only a few $\times 10^5$ yr. Their rarity belies their importance. All stars more massive than approximately $25M_{\odot}$ (for solar metallicity) pass through a W–R phase. Further, over the lifetime of a galaxy, W–R stars (and their progenitors) have an important influence on the energetics, dynamics and chemical evolution of the interstellar medium.

W–R stars are expected to end their life via a spectacular supernovae explosion. In some cases a neutron star is formed, while for the more massive stars a black hole is formed. In the latter case the details of the mechanism that actually produces the supernova are still very uncertain. As the supernovae ejecta expands, it will interact with the complex circumstellar environment that reflects the previous mass loss history of the progenitor star.

In addition to the population I W–R stars, some planetary nebula central stars also show W–R emission features (see PLANETARY NEBULA CENTRAL STAR MASS LOSS/WINDS, W–R NEBULA). Their spectral types are inserted in [] to distinguish them from population I W–R stars. They are of type [WC] and have lower masses (less than $1M_{\odot}$) and lower luminosities (generally $<3 \times 10^4 L_{\odot}$). The spectra of planetary nebula W–R stars are often dominated by strong narrow nebula emission lines. In some cases they can be difficult to distinguish spectroscopically from normal population I W–R stars although in some [WC] stars N and H emission is seen. Because of their distinct evolutionary histories, they will not be further discussed in this article.

Basic model

The basic model for W–R stars is that of a hot star which is suffering extreme mass loss. The mass loss occurs via a continuous stellar wind which is accelerated from low velocities near the surface of the star to velocities that exceed the surface escape speed. The observed spectrum originates over a range of radii with the optical continuum forming close to the stellar core, while the emission lines originate from a volume that can extend beyond 10 stellar radii.

The observed mass-loss rates (i.e. the amount of material lost per year) are extreme, typically in excess of $10^{-5} M_{\odot}$ yr^{-1}. These mass-loss rates are sufficient to affect the evolution of the star (see STELLAR EVOLUTION) and must be incorporated into stellar evolutionary calculations. The (average) maximum velocity of material in W–R winds (called the terminal velocity, V_{∞}) ranges from 800 km s^{-1} to in excess of 3000 km s^{-1}, and typically exceeds the escape velocity from the surface of the star. It is generally believed, although it has yet to be rigorously demonstrated, that the mass loss is driven by radiation pressure acting through numerous bound–bound atomic transitions of Fe and other atomic species in the extreme UV ($\lambda < 900$ Å).

The bulk of the material in the wind is believed to be cool—that is, it has a temperature substantially lower

[1] He II is a spectroscopic designation used to indicate the ion for a transition between bound levels in singly ionized helium (i.e. He^+).

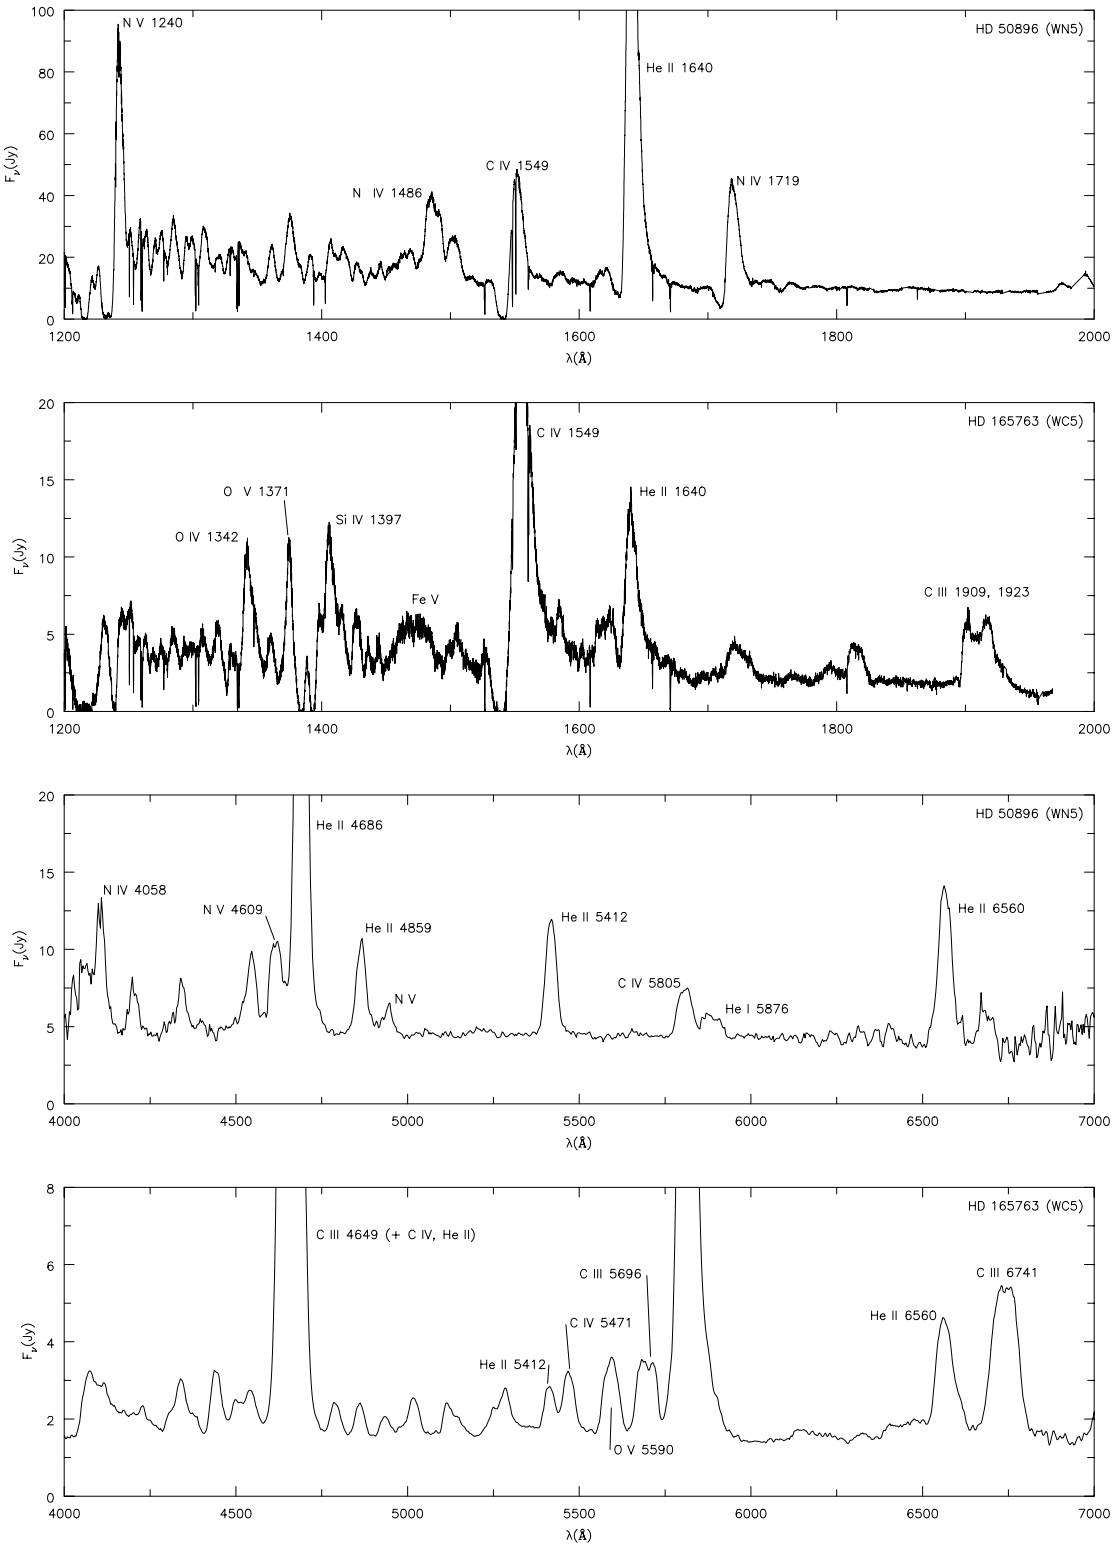

Figure 1. UV and optical spectra of the WN5 star HD 50896 and the WC5 star HD 165763. The major emission line features are identified, although it should be noted that many lines, particularly in the WC star, are blends. Notice the very distinct differences between the WN5 and WC5 spectra. The optical spectral region, which can be observed from the ground, has typically been used to classify W–R stars. Since the advent of space astronomy, the UV spectral region has provided additional invaluable diagnostics on the properties of W–R stars.

than the effective temperature of the star. Energy input into the wind primarily occurs through photoionization by the intense UV radiation field emanating from the central source. Thus photoionization is the ultimate source of the line emission that originates in the wind, although individual emission lines form through a variety of different processes—recombination, collisional excitation and continuum fluorescence.

Determination of stellar parameters

The spectra of most stars are determined by three basic parameters: the effective temperature ($T_{\rm eff}$), the effective surface gravity ($g_{\rm eff}$) and the chemical abundances. For an assumed metallicity, large grids of models can be constructed simply by varying $T_{\rm eff}$ and $g_{\rm eff}$.

The effective temperature is defined by the relation

$$L = 4\pi R_*^2 \sigma T_{\rm eff}^4$$

where L is the luminosity and σ is the Stefan–Boltzmann constant. The effective temperature is the surface temperature that a star of radius $R_\star$ would have if it radiated as a blackbody (a perfect thermal emitter and absorber).

The effective surface gravity is defined by

$$g_{\rm eff} = (1-\Gamma)\frac{GM}{R_\star^2}$$

where M is the star's mass, G is Newton's gravitational constant, and Γ is a correction for the influence of radiation pressure. In conjunction with the equation of hydrostatic equilibrium

$$\frac{{\rm d}P}{{\rm d}r} = -\rho g_{\rm eff}\left(\frac{R_\star}{r}\right)^2$$

where P is the pressure and ρ is the density, this sets the scale height of the atmosphere, $h_\star$. For an isothermal atmosphere, $h_\star$ is given by

$$h_\star = \frac{kT}{\mu m_{\rm H} g_{\rm eff}}$$

where μ is the mean particle mass in atomic mass units (amu) and $m_{\rm H}$ is the atomic mass of hydrogen. For most normal stars $h_\star \ll R_\star$, curvature effects can be ignored and the atmosphere can be treated as a plane-parallel slab. As a consequence of the small scale height, the Sun has a definite radius at optical wavelengths.

For W–R stars the situation is quite different. First, the atmosphere is extended, and consequently radiation escapes from the star over a range of radii. Further, the radius of the star at an optical depth (τ) of 2/3 depends on the adopted mass-loss rate and is a function of wavelength (figure 2). The difficulty of uniquely defining $R_\star$ has led to difficulties in comparing $T_{\rm eff}$ derived from evolutionary models with that obtained from spectroscopic analyses. Second, $g_{\rm eff}$ does not have a direct influence on the stellar spectrum, simply because emission from the stellar wind dominates the spectral appearance of the star. Third, the abundances are non-solar and must be determined observationally. Indeed it is the abundances that determine to which class (WN, WC or WO) a W–R star belongs (see also STELLAR ATMOSPHERES: EARLY-TYPE STARS).

In addition to the abundances (primarily of H, He, N, C and O) it has been found from numerical experiments that the spectra of W–R stars are determined primarily by two parameters: $T_{\rm eff}$ and a wind density parameter, W_ρ. The latter, which plays a similar role to $g_{\rm eff}$, can be defined by

$$W_\rho = (\dot{M}/V_\infty)R_{\rm c}^{-3/2}$$

where $R_{\rm c}$ is the radius of the hydrostatic core. Two stars will have very similar spectra if they have similar abundances, and if $T_{\rm eff}$ and W_ρ are similar. The dependence of the spectra on W_ρ arises because most of the radiative processes in an extended atmosphere depend on the square of the density. As a consequence of the scaling, it is impossible to deduce the distance of a W–R star from the Sun using its spectrum[2]. In principle, $\dot{M}$ and V_∞ should depend on the other stellar parameters—composition, M, L and $R_\star$, but as yet our theoretical understanding of mass loss from W–R stars is not sufficiently advanced to deduce the relationship.

Because of the low wind densities (10^8–10^{14} electrons cm^{-3})[3] the simplifying assumption of local thermodynamic equilibrium (LTE) cannot be made when modeling W–R spectra. When LTE holds, it can be assumed that the ionization state of the gas and the populations of the atomic levels can be found via application of the principles of statistical mechanics and thus are (simple) functions of the local temperature and density only. For LTE to prevail, collisional processes, which couple the atomic populations with the electrons (and hence to the local electron temperature), need to occur faster than radiative processes.

In contrast, in W–R atmospheres radiative processes tend to dominate over collisional processes, and hence it is necessary to solve the equations of statistical equilibrium at each depth. For each atomic level of each species we assume that all the processes (radiative and collisional) populating the level are in equilibrium with all processes depopulating the same level. The major difficulty arises because the rates are a function of the radiation field, which in turn is a function of the unknown populations. Thus the radiation field and atomic populations must be solved for simultaneously, and in general an iterative procedure is necessary to obtain consistency.

[2] Stellar evolution introduces a correlation between spectral type and luminosity which may statistically allow distances to be derived for stars of a given spectral type. However, for an individual star the derived distance may be grossly in error, particularly if the spectral type can originate via different evolutionary sequences. This is exemplified in the difficulty of determining whether some W–R stars belong to population I or are the central stars of planetary nebula.

[3] For comparison, the density of water on Earth is of order 10^{22} molecules cm^{-3}.

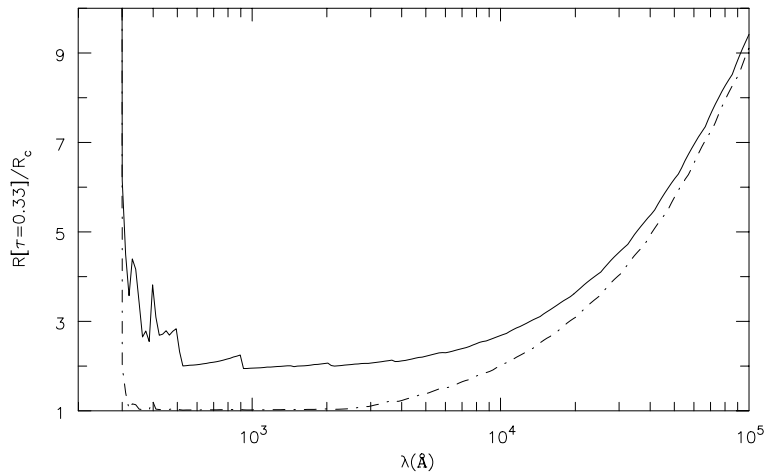

Figure 2. Illustration of how the 'radius' of the star varies with wavelength for the WC5 star HD 165763. The solid curve shows the 'radius' at which the 'continuum' optical depth, τ, is 1/3, which occurs in the wind at all wavelengths. The broken curve is identical except that the electron scattering opacity was not included in the computation of τ. The bulk of the observed flux in this model is emitted between 300 and 2000 Å. R_c is the radius of the hydrostatic core—that is, the approximate radius the star would have in the absence of a stellar wind. For the illustrated model it was $1.8R_\odot$.

Initial modeling of W–R spectra concentrated on the H and He spectra only. The second generation included CNO elements, while the most recent generation of models include iron and other species. The inclusion of iron (and similar species) in non-LTE calculations has been a major stumbling block for atmospheric calculations for O and W–R stars for many years. The iron-group ions have both a wealth of atomic levels and an enormous number of bound–bound transitions. The advent of faster computers with large memories, new numerical techniques and the availability of atomic data have now made it feasible to include iron and other species in non-LTE calculations.

Determination of $T_{\rm eff}$

The effective temperatures of W–R stars are determined primarily using ionization arguments. Consider a sequence of models with prescribed mass loss and velocity law, but with different effective temperatures. Such a sequence of models will exhibit a smooth variation in line ratios for lines from two successive stages of ionization. In early WN modeling it was customary to compare He II 5411 with He I 5876 since both lines are easily observed and are relatively blend free. In more recent modeling N lines can also be used to constrain the effective temperature, while in WC stars C and O lines can be used. The analyses generally give consistent results. Discrepant results do occur, and probably result from a poor treatment of line blanketing (the generic name given to the influence of thousands of bound–bound atomic transitions on an atmosphere) and/or density inhomogeneities in the stellar wind.

Analyses of the spectra of ring nebula around W–R stars offers a method of checking on the energy distributions predicted by atmospheric modeling, since the nebula are ionized by the star's radiation field. For ring nebula around WNE stars these analyses have usually shown reasonable consistency. However, for some WNL and WC stars the observed nebular spectrum was of lower excitation than would be predicted using the stellar UV radiation field derived from the modeling. The recent inclusion of line blanketing in the stellar atmospheric models has removed this discrepancy for at least one ring nebula around a WN8 star.

Abundances

The severe non-LTE conditions in W–R stars initially made it difficult to understand their peculiar emission line spectra. Do W–R stars possess peculiar (i.e. non-solar) abundances? Is the difference between the WN and WC stars due to an abundance difference, or is it an excitation effect? Detailed recombination and spectroscopic analyses have now firmly established that W–R stars are characterized by non-solar abundances.

In WN stars H, C and O are depleted, while N and He are enhanced. For WN stars, $N(\mathrm{H})/N(\mathrm{He})$ ratios (by number) range from approximately 4 to <0.1 (the solar value is 10). The observed abundances are consistent with the idea that material processed by the CNO nuclear burning bi-cycle has been revealed (or mixed) at the surface (see 'Evolution').

In WC stars, He, C, O and Ne are all enhanced. $N(\mathrm{C})/N(\mathrm{He}) = 0.1$–$0.5$ while the less certain $N(\mathrm{O})/N(\mathrm{He})$ ratios are typically 0.1. H and N are not expected in WC stars and are not detected. The variation of $N(\mathrm{C})/N(\mathrm{He})$ and $N(\mathrm{O})/N(\mathrm{He})$ with WC subtype is still the subject of much debate.

Determination of mass-loss rates

Mass-loss rates can be determined in several ways. First, free–free radiation in the dense stellar wind gives rise to a detectable flux at radio wavelengths. From measurements of the radio flux, S_ν, the mass-loss rate, $\dot{M}$, can be determined from the simple formula

$$S_\nu = 23.2\left(\frac{\dot{M}z}{V_\infty \mu}\right)^{4/3}\left(\frac{\gamma g \nu}{d^3}\right)^{2/3}$$

where d is the distance to the W–R star in kpc, $\dot{M}$ is the mass-loss rate in $M_\odot$ yr^{-1}, V_∞ is the terminal velocity of the wind in km s^{-1}, z is the mean ionic charge, μ is the mean ionic mass (in amu), γ is the number of electrons per ion, ν is the frequency in Hz and g is the free–free Gaunt factor (which is the quantum correction factor to the semiclassical formula for free–free radiation) at frequency ν. S_ν is measured in janskys (1 jansky $= 10^{-23}$ erg cm^{-2} s^{-1} Hz^{-1}). The greatest uncertainties in the derived $\dot{M}$ arise from uncertainties in stellar distance and in the ionization state of the gas in the radio-emitting region.

Second, the IR flux can be used in a similar manner, although in this case it cannot be assumed that the wind has reached its terminal speed. Third, optical and UV emission lines can be used. Typically, recombination lines are used since they are less sensitive to the precise details of their formation. Mass-loss estimates obtained from different methods generally agree to within a factor of 2.

It has generally been assumed that the winds of W–R stars are spherical and homogeneous. Thus at any location in the wind the density can simply be found from the principle of mass conservation, giving

$$\rho = \frac{\dot{M}}{4\pi r^2 v(r)}$$

where $v(r)$ is the velocity as a function of distance and is assumed to monotonically increase with r. However, emission line variability studies and analyses of emission line profiles suggest that the wind is clumped (i.e. non-homogeneous) on small scales. If this is true, mass-loss estimates are too large—possibly by factors of 3 or more. This has very important implications for stellar evolution calculations. A change in $\dot{M}$ by only a factor of 2 (over a star's life) has a profound influence on the evolution of massive stars. This is seen in theoretical evolutionary calculations and can also be indirectly inferred from the different WN/WC ratios in the galaxy and our nearest extragalactic neighbor, the Large Magellanic Cloud (LMC). In the LMC the mass-loss rates are expected to be lower because of the lower metallicity.

The extreme mass-loss properties of W–R stars can be characterized by the 'wind performance parameter', η, defined by

$$\eta = \frac{\dot{M}V_\infty}{L/c}.$$

$\dot{M}V_\infty$ is the (scalar) momentum of the wind, while L/c is the momentum that could be transferred if all the photons, and hence all the momentum in the radiation field, were absorbed. For O stars, η is typically less than unity. For W–R stars values as high as 100 have been obtained, although by allowing for inhomogeneities and line blanketing it has been possible to reduce the values to less than 10. Values of η in excess of unity do not rule out a radiation-driven wind—they simply indicate that each photon has to scatter many times within the wind so that it delivers η times its momentum to the wind. It has been difficult to produce radiation-driven winds for W–R stars since current models do not have the necessary number of bound–bound atomic transitions to perform the required number of scatterings.

Binaries

Approximately 50% of W–R stars occur in binaries—a number comparable with O stars. In the past there has been considerable discussion on the importance of binarity for the W–R phenomenon. For example, it was once thought that W–R stars could only originate in a binary system. Mass loss from the W–R progenitor would then occur by Roche-lobe overflow. The major uncertainty in evolutionary calculations of binary systems is how much material is lost from the system during Roche-lobe overflow (rather than being accreted by the companion). More recently the binary channel for the production of W–R stars has virtually been ignored. There is little doubt, however, that the binary channel is important, and it must be considered when linking W–R types with evolutionary calculations (although many researchers would disagree with this statement).

At least three (broad) distinct classes of W–R binary systems can be envisioned: W–R + OB star, W–R + W–R, W–R + compact companion (neutron star or black hole). All (confirmed) W–R binaries belong to the first class; W–R + W–R systems are expected to be rare, although WR98 (where WR98 denotes the 98th W–R star in the sixth catalogue of W–R stars) may be an example of such a system. The third class is expected on evolutionary grounds. Although the existence of such systems has been difficult to verify, several good candidate systems are known. Cyg X-3 can be considered a possible example.

W–R binary systems are extremely useful. First, and foremost, they allow a direct determination of stellar masses, independent of evolutionary models. The use of these masses in constraining single-star evolutionary models presupposes that W–R stars in binaries have properties similar to single W–R stars—a proposition that cannot be reliably tested because of poor statistics and uncertainties in the properties of W–R stars.

Second, the O star can be used to probe the structure of the W–R stellar wind. Indeed it was this technique, applied to the W–R + O binary V444 Cygni, which gave the first direct evidence that W–R stars are hot (i.e. surface temperature in excess of 60 000 K). More recently it has become evident that polarization studies of binary systems may allow determinations of mass-loss rates which are insensitive to the presence of inhomogeneities within the stellar wind.

X-ray emission

Most W–R stars are thermal x-ray sources. They can be classified into two categories—single W–R stars and binary W–R stars. In single W–R stars the observed ratio of x-ray to bolometric luminosity is approximately 10^{-7}, although there is a scatter of at least a factor of 3 about this value. The x-rays are believed to originate within the stellar wind through radiation-driven wind instabilities which lead to high-velocity shocks ($V_{\rm shock}$ = 100–600 km s^{-1}) and clumping of the wind. These shocks generate x-ray emitting gas characterized by temperatures between 10^6 and 10^7 K. The shocks probably permeate most of the wind; however, because of the high wind densities most of the x-rays are absorbed in the wind.

A few W–R stars are stronger and/or variable x-ray emitters. In these binary systems the x-rays can be generated from the high-temperature gas (of order 10^7 K) created via shocks generated in a wind–wind collision. The two best examples are the WN + O system V444 Cygni and the WC + O system HD193793 (WR140). Both exhibit a periodic x-ray variability broadly consistent with that expected from a wind–wind collision in a binary system. Alternatively the x-rays could be generated via accretion of wind material onto a compact companion.

Dust formation

This topic, by all rights, should not belong in a discussion on W–R stars since dust is destroyed by intense UV radiation and requires low temperatures (<3000 K) for its formation. Yet dust is seen around some WC stars, and moreover dust is seen to be created in the vicinity of some WC stars. Two distinct dusty WC classes may exist: binary systems and single stars.

In many WC9 stars, presumed to be single, conditions within the C-rich stellar wind appear to allow dust formation. The dust nucleation routes and how the dust (and the necessary prerequisite molecules) forms despite the presence of an intense UV radiation field are unclear. If the stars are single, inhomogeneities generated by radiation instabilities probably play an important role in allowing dust to form.

The second class are the binary systems, with eccentric orbits, with HD193793 (WR140) being an excellent example. In these systems dust does not normally form; however, binary interaction near periastron (i.e. minimal orbital separation) can facilitate dust formation. Apparently the high densities generated in the wind–wind interaction have the right conditions for dust formation. As in the single WC stars, the dust formation is not understood.

Recent interferometric observations of WR104 with the KECK telescope have revealed directly the dust outflowing from the interaction region of the binary (figure 3).

Figure 3. A gray scale image at 2.27 μm showing the distribution of dust in WR104, as found by interferometric observations with the KECK telescope. The dust moves away from the system radially—the apparent spiral motion is an illusion. It results from the rotation of the dust formation zone as a consequence of the orbital motion of the binary system. The ring of dust, as illustrated, has an angular diameter of approximately 160 AU (or 0.1 arcsec). (Picture courtesy of W Danchi, J Monnier and P Tuthill, Berkeley.)

Related stars

In the upper part of the Hertzsprung–Russell (H–R) diagram, many different classes of massive luminous stars exist (see HIGH-LUMINOSITY STARS): Of stars, blue supergiants (BSGs), red supergiants (RSGs), LUMINOUS BLUE VARIABLES (LBVs) and WN/Of stars. One of the goals of massive star evolution is to understand the links between the various classes of objects and the distribution of massive stars between the different classes. Below we briefly discuss some of the salient features of each class.

Of stars are O supergiants exhibiting emission lines in the optical. They are O stars that have evolved off the main sequence. WN/Of stars exhibit spectral characteristics of both Of and WNL stars. It was this intermediate characteristic that suggested an evolutionary link between the Of stars, and bona-fide WN stars.

LBVs, as their name suggests, are luminous blue stars which show irregular variability on a time scale of hours to centuries. Some LBVs have exhibited giant outbursts in which their visual brightness and bolometric magnitude increased by several magnitudes. During such outbursts several solar masses of material may be ejected. Other LBVs, such as AG Car, show moderate outbursts on a timescale of a decade. During these outbursts the effective temperature changes but the bolometric luminosity and mass-loss rate are almost constant. The most famous LBVs are P Cygni, which suffered a giant outburst in the 1600s, and η Car which underwent a major outburst in the 1840s. The outburst suffered by η Car ejected a bipolar nebula, referred to as the Homunculus, which has a major axis diameter of 17″ (approximately 4000 AU). Images of the Homunculus are amongst the most spectacular obtained by the Hubble Space Telescope.

A major breakthrough in our understanding of massive stars was achieved when one LMC Of/WN star (now classified as WN11), R 127, was observed to undergo an LBV-like outburst, suggesting an evolutionary link between LBVs and Of/WN stars.

LBVs are now regarded as a key phase of massive star evolution. It is believed that during the LBV phase a massive star ejects most of its hydrogen-rich outer envelope, allowing it to become a W–R star. A key observation that has led to this scenario is the absence of RSGs with luminosities comparable with the most luminous O stars. Evolutionary calculations show that, during the LBV phase, extensive mass loss can prevent the star from evolving into an RSG. The mechanism of mass loss during the LBV phase is not yet understood, although it may be related to the star evolving towards the modified Eddington limit. The classical Eddington limit provides a lower limit on the mass of a star, of a given luminosity, based on the assumption that the radiative force arising from the electron scattering opacity cannot exceed gravity. The modified Eddington limit takes into account that other radiative processes also contribute to the opacity, and further that stellar rotation can effectively lower the surface gravity. The maximum luminosity exhibited by supergiants in the H–R diagram is termed the Humphreys–Davidson limit.

Evolution

W–R stars are believed to be descended from O stars. The basic evolutionary sequence, first proposed by Conti in 1976, is

$$\mathrm{O} \rightarrow \mathrm{Of} \rightarrow \mathrm{W\text{–}R}$$

Since that time observational and theoretical work has led to refinements in this basic sequence. From the theoretical work of Maeder and collaborators, one such sequence for stars with initial masses greater than $50M_{\odot}$ is

$$\mathrm{O} \rightarrow \mathrm{OIf} \rightarrow \mathrm{BSG} \rightarrow \mathrm{LBV} \rightarrow \mathrm{WN} \rightarrow \mathrm{WC} \rightarrow \text{supernova}$$

while stars between $35M_{\odot}$ and $50M_{\odot}$ have the alternative sequence

$$\mathrm{O} \rightarrow \mathrm{BSG} \rightarrow \mathrm{YSG} \rightarrow \mathrm{RSG} \rightarrow \mathrm{YSG} \rightarrow \mathrm{WN} \rightarrow \mathrm{WC} \rightarrow \text{supernova}.$$

Other sequences have also been proposed. Suffice it to say that the precise evolutionary path that an individual massive star follows (which depends on the star's initial mass and composition, and possibly its rotation rate and whether it has a companion) is still uncertain. No firm link has been established between the different ionization classes within the WN and WC sequences, although there has been some success in linking spectral types with initial stellar mass. The unknown roles of binary interactions and rotation only add to the confusion.

Both WN stars and WC stars are generally believed to be on the helium-burning main sequence, although some of the luminous hydrogen-rich WN stars may still be core hydrogen burning. If the latter is true, it means that the spectroscopic and theoretical definitions of W–R stars are inconsistent. This creates difficulties in comparing observed W–R/O number ratios with theoretical predictions. The W–R/O ratio is an important observational constraint since it provides a method (at least in principle) of determining the minimum stellar mass which will evolve into a W–R star. For a solar metallicity this is generally believed to be approximately $25M_{\odot}$, but higher values cannot be ruled out.

In massive stars, H burning occurs via the CNO bi-cycle through a sequence of reactions, with the CNO species acting as catalysts. In the CN cycle the following reactions occur:

$$\begin{aligned}
{}^{12}_{6}\mathrm{C} + {}^{1}_{1}\mathrm{H} &\rightarrow {}^{13}_{7}\mathrm{N} + \gamma \\
{}^{13}_{7}\mathrm{N} &\rightarrow {}^{13}_{6}\mathrm{C} + \mathrm{e}^{+} + \nu \\
{}^{13}_{6}\mathrm{C} + {}^{1}_{1}\mathrm{H} &\rightarrow {}^{14}_{7}\mathrm{N} + \gamma \\
{}^{14}_{7}\mathrm{N} + {}^{1}_{1}\mathrm{H} &\rightarrow {}^{15}_{8}\mathrm{O} + \gamma \\
{}^{15}_{8}\mathrm{O} &\rightarrow {}^{15}_{7}\mathrm{N} + \mathrm{e}^{+} + \nu \\
{}^{15}_{7}\mathrm{N} + {}^{1}_{1}\mathrm{H} &\rightarrow {}^{12}_{6}\mathrm{C} + {}^{4}_{2}\mathrm{He}.
\end{aligned}$$

The fourth reaction is the slowest, and as a consequence much of the original C (and O from the other reactions in the CNO bi-cycle) is converted to N. The total number of CNO nuclei remains unchanged. When equilibrium is obtained, the ratio of ^{14}N to ^{13}C nuclei is approximately 50, very different from the solar ratio of 0.27.

In normal stars the nuclear processed material remains within the stellar core and cannot be observed. However, in O stars and their descendants, extensive mass loss peels off the outer hydrogen-rich layers. Nuclear processed material, once inside the convective core of the star, is eventually revealed at the surface. In addition to mass loss, it is now believed that mixing, possibly induced by stellar rotation, can help reveal nuclear processed material at the stellar surface.

In WC stars the mass loss has been so extensive that the products of He burning are revealed at the stellar surface. The predominant reactions for helium burning are

$$\begin{aligned}
{}^{4}_{2}\mathrm{He} + {}^{4}_{2}\mathrm{He} &\rightleftharpoons {}^{8}_{4}\mathrm{Be} \\
{}^{8}_{4}\mathrm{Be} + {}^{4}_{2}\mathrm{He} &\rightarrow {}^{12}_{6}\mathrm{C} + \gamma \\
{}^{12}_{6}\mathrm{C} + {}^{4}_{2}\mathrm{He} &\rightarrow {}^{16}_{8}\mathrm{O} + \gamma.
\end{aligned}$$

The variation in surface abundances as a function of current mass for a star with an initial mass of $40M_{\odot}$ is shown in figure 4.

W–R stars in external galaxies

W–R stars are moderately easy to detect in external galaxies owing to their strong emission lines. Typically they are found by performing a photometric survey in two filters. The passband of one filter is centered on a strong emission feature (generally the He II–C III/C IV complex at 4640–4690 Å) while the second passband is centered on

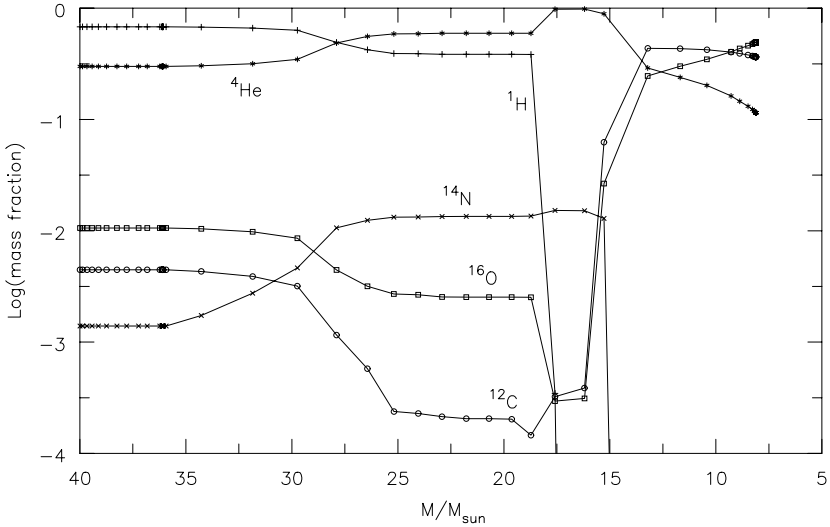

Figure 4. A diagram showing the evolution in surface abundances as a function of mass for a star with an initial mass of $40M_{\odot}$. The WN phase occurs when the star's mass is between (approximately) $15M_{\odot}$ and $30M_{\odot}$, while the WC phase occurs when $M < 15M_{\odot}$. For most of its 4.8×10^6 yr life the star has a mass close to its initial value (e.g. after 4.2×10^6 yr, its mass is still $\approx 36M_{\odot}$). The lifetimes of various stages are very dependent on the adopted assumptions (e.g. overshooting and mixing) and the adopted mass-loss rates. Overshooting refers to the phenomenon of convective motions extending into a convectively stable region because the convective velocities are non-zero at the interface between the convectively stable and unstable regions. Mixing refers to the process of mixing two chemically distinct regions of the star—for example rotation might induce nuclear processed material to be transported to the surface layers. The calculations were undertaken by the Geneva group (Maeder, Meynet, Schaller and Schaerer) for solar metallicity, with overshooting and 'normal' mass-loss rates.

the continuum only. W–R stars will be relatively bright in the emission line passband. Alternatively, they can be found using low-dispersion prism spectroscopic surveys.

Both the Large Magellanic Cloud (LMC) and the Small Magellanic Cloud (SMC) have been extensively surveyed for W–R stars. In the LMC 134 W–R stars are known, while in the SMC only nine are known. The difference in the number of W–R stars is believed to be due to a combination of the star formation rates and the lower metallicity of the SMC (which inhibits W–R production). Interestingly, the ratio of WN to WC stars in the LMC is 4.5, substantially larger than the observed ratio of 1 in the solar neighborhood. This is generally interpreted as a metallicity effect.

W–R stars have also been found in many Local Group galaxies, e.g. M31, M33, IC1613 and NGC6822. The study of individual W–R stars in these galaxies is in its infancy. To date, efforts have been directed primarily into determinations of the WN/WC, O/W–R and RSG/W–R number ratios which allow global issues, such as the effect of metallicity and the star formation rate on W–R production, to be addressed.

W–R stars have also been found in many galaxies exhibiting extensive star formation (often called STARBURST GALAXIES). Indeed some galaxies are termed W–R galaxies if they exhibit strong W–R features in their integrated spectra. The presence of W–R stars in these galaxies immediately provides an age determinant. The starburst has to be older than approximately 2 million years so that the most massive O stars that formed in the burst have had sufficient time to evolve into W–R stars. They also provide an upper limit of about 7 million years since after this time all massive stars that pass through a W–R stage will have done so. Both age limits are metallicity dependent.

Outstanding problems

There are many outstanding problems related to W–R research. Several of the most important problems related specifically to W–R stars are discussed below.

(1) What initiates and drives mass loss from W–R stars? Is radiation pressure, as currently believed, responsible for mass loss from W–R stars? Why are mass-loss rates for W–R stars an order of magnitude higher than those of their O star progenitors?

(2) What is the role of rotation in W–R stars (and their progenitors) in modifying the spectral appearance of the star? What is the role of rotation in massive stars in enhancing mixing processes and in enhancing mass-loss rates, and hence in modifying stellar evolution?

It is essential for evolutionary calculations, whatever the mass-loss mechanism, that we are able to derive mass-loss rates from first principles. Ideally

$$\dot{M} = \dot{M}[M_{\rm init}, t, x, y, z, \Omega(t)]$$

where $M_{\rm init}$ is the initial stellar mass, t is the current age of the star and x, y and z are the chemical

abundances (hydrogen mass fraction, helium mass fraction and metal mass fraction), and where the rotation rate $\Omega(t)$ is itself determined via the initial rotation rate and the subsequent mass loss.

A related question is the role of magnetic fields in massive star evolution. While the magnetic fields may be too weak to affect mass-loss rates they could be important in determining angular momentum losses, and hence play an indirect role in mass loss through the dependence of $\Omega(t)$ on magnetic field strengths.

(3) What is the detailed structure of W–R winds (shape and homogeneity)? How does the presence of inhomogeneities affect the determination of the fundamental stellar parameters? How coupled is the mass loss to the details of the wind structure?

(4) What is the role of binaries in massive star evolution? Are there classes of W–R stars (and LBVs) that only come from a binary evolutionary scenario? How much is our understanding of single-star evolution being confused by the evolution of OB stars in interacting binary systems?

(5) Because of uncertainties in the treatment of convection, mass-loss processes and rotation, there are still many issues in single-star evolution which must be addressed. Also of concern is whether W–R stars give rise to black holes (as presumed), and to what class a W–R supernova belongs.

Acknowledgments

This contribution is a brief synopsis of our current understanding of W–R stars. This understanding is the cumulative result of 130 years of W–R research by many astrophysicists whose individual contributions cannot be acknowledged.

Wollaston, William (1766–1828)

Chemist and physicist, isolated two new metals from platinum ore, one of which he named palladium (after the newly discovered asteroid, Pallas). He was one of the first scientists to observe ultraviolet radiation, and in 1801 discovered the dark spectral lines in the solar spectrum which were later investigated by FRAUNHOFER. This was the first observation of spectral lines. A *Wollaston prism* is used to study the polarization of light.

Woolley, Richard van der Riet (1906–86)

Astronomer, born in Dorset, England, and followed a varied career in England, South Africa, California and Australia. Became director of the Commonwealth Solar Observatory and steered it away from solar observations and wartime optics work to become the Mount Stromlo Observatory and part of the Australian National University. He worked on stellar and solar atmospheres. In 1955 he became Astronomer Royal in Britain, directing the Royal Greenwich Observatory in Sussex. He worked there on the motions and astrophysics of stars and clusters of stars, directing a small army of workers on the measurements of star positions on the thousands of photographic plates that he caused to be taken. He discovered the orbit of the globular cluster Omega Centauri, which moved radially in the Galaxy. He caused the Isaac Newton Telescope to be erected at Herstmonceux: it was later moved to the clearer sky of La Palma. He retired from the Royal Greenwich Observatory and became director of the South African Astronomical Observatory at the Cape.

Wormhole

A hypothetical shortcut, or 'tunnel', that, in principle, may link the interior of a black hole to another universe or to another location in our universe. During the 1930s, Albert Einstein (1879–1955) and Nathan Rosen (1909–95) showed that the sharply curved spacetime of the interior of a black hole may open out again into another spacetime (another universe). The hypothetical connection between these two regions of spacetime came to be known as an Einstein–Rosen bridge. An alternative interpretation is that the bridge, or tunnel, links two different regions in the spacetime of our own universe. More recently, the term 'wormhole' has been used to describe a spacetime tunnel of this kind. Although it has been speculated that wormholes could be used to facilitate virtually instantaneous interstellar travel, in practice it seems likely that, even if wormholes do exist, they will be too small and too short-lived (and too physically hazardous) to be utilized in this way.

Wren, Sir Christopher (1632–1723)

Architect and astronomer, born in East Knoyle, Wiltshire, became professor of astronomy at Gresham College, and Savilian Professor of Astronomy at Oxford. He rebuilt London after the fire of 1666, planning the entire city and rebuilding 51 churches, including St Paul's Cathedral. Newton acknowledges Wren as a mathematician in the *Principia*. Wren independently proved KEPLER's third law and formulated the inverse-square law of gravitational attraction. He solved *Kepler's problem* on cutting a semicircle in a given ratio by a line through a given point on its diameter (it had arisen as a problem in Kepler's work on elliptical orbits). Wren was a founder member of the Royal Society, and its president for two years.

Wright, Thomas (1711–86)

English astronomer, born near Durham, clock-maker and mathematics teacher, wrote in 1750 a curiously argued book in which he suggested that the Milky Way was a disk-like system of stars with the solar system near the center. Wright suggested that nebulae were star systems similar to the Milky Way, but very far away. Conjectured that the gap in the planets between Mars and Jupiter had been cleared by the collision of a comet with a planet which had then been ejected from its orbit.

Wrinkle Ridge

A long ridge on the surface of a planetary body. Wrinkle ridges were first identified on the Moon, where they are often associated with rilles. As the lunar maria solidified, tensile forces in the outer regions opened up the faults that produced rilles, while compressive forces nearer the center pushed up the surface to form wrinkle ridges. Some wrinkle ridges may result from small-scale extrusion of lava along fissures; others extend from the maria into surrounding upland terrain. Lunar wrinkle ridges are typically several hundred meters high and several hundred kilometers long. On Venus wrinkle ridges are common features on the plains, where they extend for 10 to 50 km. The alignment of many of them suggests that they are associated with the compressive forces that uplifted the northern upland region of Aphrodite Terra.

Xenocrates of Chalcedon (396–314 BC)

Philospher and mathematician, born in Chalcedon (now Kadikoy, near Istanbul), Bithynia (now Turkey), succeeded Speusippus as head of the Athenian Academy which PLATO had founded. Believed that matter is composed of indivisible units (and thus an early atomist). He believed (and perhaps originated the notion) that people have a threefold existence, mind, body and soul, and that they die twice, once on Earth, then on the Moon, when the mind separates from the soul and travels to the Sun.

X-Ray Astronomy

X-ray astronomy is an achievement of the space age as the Earth's atmosphere is completely opaque at photon energies beyond the ultraviolet region.

In 1949 the first X-RAYS from the solar corona were detected by a Geiger counter on a V-2 rocket. In 1962 the discovery of the first x-ray source outside the solar system followed—SCORPIUS X-1. With the same rocket experiment an apparently diffuse x-ray background was found. Since these early days x-ray astronomy has developed at an enormous pace. Today, we know more than 150 000 x-ray sources in the sky and they include almost all astrophysical species—from the nearby comets to the most distant quasars at the edge of the universe, from the tiny neutron stars to the clusters and superclusters of galaxies as the largest physical formations in the cosmos. Some species radiate most of their power in x-rays, for instance black holes or neutron stars accreting matter from a binary companion, as well as supernova remnants and single, cooling neutron stars.

Many of the known objects shine in x-rays because they are hot—having temperatures of millions to billions of kelvins. Other emission mechanisms are synchrotron radiation of extremely energetic electrons spiraling in magnetic fields or the inverse Compton effect which occurs when high-energy electrons scatter at low-energy photons, e.g. from stellar light or from the 2.7 K cosmic background radiation. In any case, the emission of x-rays points to extreme physical conditions in the source region. Also, these x-rays carry information which is not available from observations in other spectral bands. In this article we shall give a brief summary of the development of x-ray astronomy, describe the evolution of experimental techniques and x-ray space missions and highlight some of the results which have had a major impact on astrophysics.

The beginnings with sounding rockets

Like GAMMA-RAY ASTRONOMY, the field of x-ray astronomy was pioneered by physicists. Herb Friedman, who detected the first solar coronal x-rays in 1949, had been working previously in ionospheric physics; Giacconi and Rossi, who led the group discovering Scorpius X-1 and the x-ray background in 1962, were nuclear and cosmic ray physicists.

The instruments used in these pioneering experiments were rocket-borne Geiger counters and spectral discrimination was achieved by means of windows and filters. A little later proportional counters became the standard instrument, working in the 1–10 keV band and having a modest spectral resolution (∼20% at 5 keV). Observations were first performed by scanning the sky by spinning or precessing the rocket. Later on more sophisticated attitude control systems allowed pointed observations to be made with greatly improved sensitivities.

The first discoveries of cosmic x-ray astronomy were totally unexpected. Sco X-1 showed a luminosity many orders of magnitude larger than that of the Sun. It soon became clear that the mechanism by which such sources are powered was the infall of matter into the deep gravitational potential well of a NEUTRON STAR (as in Sco X-1) or a BLACK HOLE. Most of the few dozen sources found during the rocket era, i.e. until the end of the 1960s, were of this kind. The other major class was SUPERNOVA REMNANTS. The identification of the CRAB NEBULA as a bright x-ray source by means of a lunar occultation was one of the early highlights. Other important discoveries of this era were the x-ray pulsations of the CRAB PULSAR and the x-ray emission from the active galaxy M87 at the center of the Virgo cluster.

After the advent of x-ray satellites rocket-borne experiments with their short observation time (∼5 min) were generally not competitive any more. However, they continued to play a role as a test bed for instruments to be flown on satellites or for special observations, in particular those ones of short lead time (e.g. on the famous SUPERNOVA 1987A).

Hard x-ray balloon experiments

The rocket experiments had shown that the spectra of compact x-ray sources are quite hard, extending much beyond 10 keV. This opened up the possibility of using balloon-borne instruments as the atmosphere becomes transparent for altitudes above 40 km at high x-ray energies (>20 keV). Balloon flights offered the advantage of long-duration observations (up to 100 h) and the crystal scintillation counters used in these experiments allowed spectra to be taken up to ∼500 keV. Balloon observations were pioneered by the MIT group in the 1960s. Important results of these early years were the measurement of the Crab spectrum to high energies (∼500 keV), the discovery of variability in GX1 + 4 and the detection of a 20 min flux from Sco X-1. This field of research culminated in the 1970s with experiments of the MIT–Leiden and the Tübingen–MPE groups which flew very large detectors operating in the pointing mode. Highlights of these activities were the observation of a lunar occultation of the Crab, the discovery of a spectral break in the Cyg X-1 spectrum corresponding to a temperature of about $\sim 20 \times 10^6$ K and the discovery of cyclotron lines at ∼40 keV in the accreting neutron star Her X-1, allowing the first direct measurement of its polar magnetic field ($\sim 5 \times 10^{12}$ G).

X-ray astronomy satellites

Most significant progress in x-ray astronomy came with the advent of satellite observatories. Their ancestor, the first satellite entirely devoted to x-ray astronomy, was UHURU. Launched in 1970 it was a spinning spacecraft with a simple, but very powerful, instrument package: an array of proportional counters of 840 cm^2 area working in the 2–20 keV band. It performed the first all-sky survey and located 339 objects, mostly X-RAY BINARIES and supernova remnants, showing a strong clustering near the galactic plane. At fainter flux levels an isotropic distribution of Seyfert galaxies and clusters of galaxies was found.

Dirac House, Temple Back, Bristol, BS1 6BE, UK

The discovery of two pulsating and eclipsing x-ray binary systems, Cen X-3 and Her X-1, proved in an impressive way that these systems contained matter-accreting neutron stars. The discovery of short time variability of Cyg X-1 by Uhuru led to follow-up rocket experiments yielding accurate source positions which enabled the optical counter-part to be identified and the mass of the accreting compact object to be determined. This mass turned out to be larger than the limiting mass of a neutron star. Thus it had to be a black hole.

Uhuru also marked the beginning of an impressive series of satellites with ever-increasing capabilities listed in table 1. We cannot discuss them in detail here, but rather describe the main directions of developments.

Imaging x-ray telescopes

Imaging of x-rays is possible in different ways. Early solar observations used pinhole cameras and Fresnel zone plates, but the sensitivity of such devices is insufficient for studies of the rather weak cosmic x-ray sources. Therefore, the standard X-RAY TELESCOPES use Wolter optics which consist of paraboloidal–hyperboloidal mirrors reflecting x-rays under grazing incidence (see GRAZING INCIDENCE OPTICS). The first x-ray telescopes of this kind using x-ray film as a detector were used for solar observations from rockets and Skylab. The first x-ray satellite carrying a Wolter telescope was the Einstein observatory launched in 1979. It provided images with ∼10 arcsec resolution and represented a real breakthrough, putting x-ray astronomy on equal footing with optical astronomy.

X-ray sky surveys

All-sky surveys have traditionally been a foundation of astrophysical research, and in the era of multiwavelength astronomy their importance has dramatically increased. Such surveys provide an unbiased view of the sky, they deliver large homogeneous samples of objects and they allow rare species to be discovered. Cross correlating the surveys from different wavelength bands—e.g. optical and x-rays—is a very effective method to select sources of a certain type, e.g. active galactic nuclei and quasars.

The Uhuru and Ariel V surveys have revealed ∼350 sources in the standard x-ray band (2–6 keV). The subsequent HEAO-1 sky survey was not much more sensitive (840 sources) but widened the energy band considerably (0.1–200 keV). The limitations of all these collimated counter surveys in terms of angular resolution (<1 deg^2) and sensitivity were overcome by the German-led ROSAT which performed the first all-sky survey in soft x-rays by sweeping an imaging Wolter telescope across the whole sky. Although it took only half a year of the more than 8 yr of ROSAT's life this survey discovered 80 000 x-ray sources and located them with 25 arcsec resolution. In addition, the survey provided a complete map of the diffuse x-ray emission with 12 arcmin resolution (figure 1).

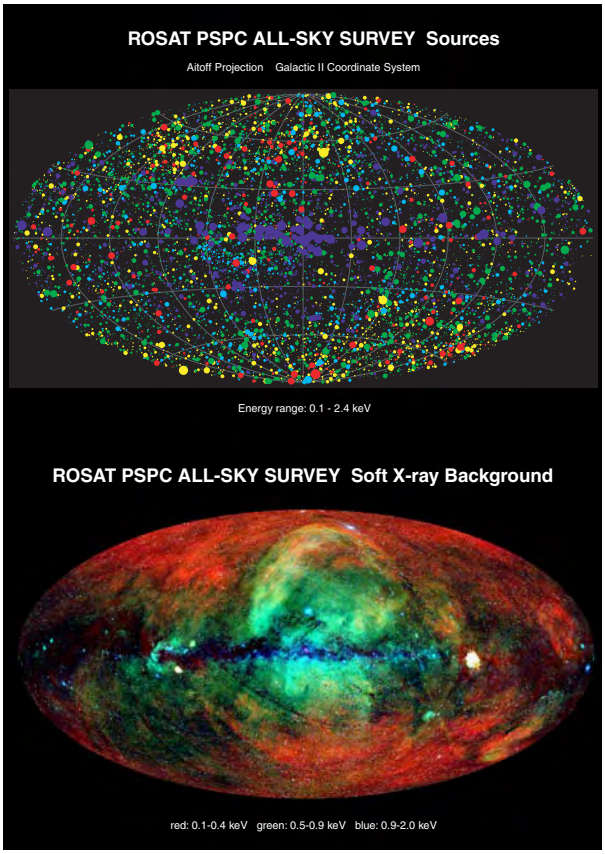

Figure 1. The x-ray sky as known at the end of the 20th century on the basis of the ROSAT All Sky Survey. Top: distribution of the ∼19 000 brightest x-ray sources; Bottom: diffuse emission from hot interstellar matter heated by supernova explosions. **This figure is reproduced as Color Plate 61.**

Recent highlights of x-ray astronomy

A rather detailed account of the development of x-ray astronomy until ∼1990 with a description of missions and their results can be found in Bradt *et al* (1992). Here we want to highlight the progress made in the 1990s by the powerful x-ray telescopes on ROSAT and ASCA.

In addition, there have been two very successful recent missions which must be mentioned here. The ROSSI Timing Explorer (RXTE) carrying large-area collimated counters covering a wide energy range (2–200 keV) has deepened our understanding of compact sources by high time resolution and spectral studies. One of its most exciting results was the discovery of 2.75 ms pulsations occurring during the bursts of the low-mass x-ray binary (LMXB) 4U 1728-34. The data suggest that the pulsation came from the rotation of a thermonuclear hotspot on the surface of the neutron star.

In another LMXB which had been previously identified as an X-RAY BURSTER by BEPPOSAX, RXTE found 2.5 ms pulsations in the persistent flux which must be due to the rotation of the neutron star. This is the first

Table 1. X-ray astronomy satellites 1969–2000. Adapted from Charles and Seward (1995) updated January 2000.

Satellite	Country	Launch	Demise	Type
Vela 5 A,B	USA	May 1969	June 1979	Scanning, small scintillation counter, gamma-ray range
Uhuru	USA	December 1970	January 1975	Scanning, proportional counters
OSO-7	USA	September 1971	May 1973	Scanning, proportional counters
Copernicus	USA–UK	August 1972	February 1981	Pointed, x-ray telescope (non-imaging)
ANS	Netherlands–USA	August 1974	July1976	Pointed proportional counters, Bragg crystal spectrometer
Ariel-V	UK	October 1974	March 1980	Scanning, rotating modulation collimators (RMCs) + proportional counters
SAS-3	USA	May 1975	April 1980	Scanning, RMC
OSO-8	USA	June 1975	October 1978	Scanning, proportional and scintillation counters, Bragg crystal, polarimeter
HEAO-1	USA	August 1977	January 1979	Scanning + short pointings, proportional and scintillation counters, RMC
Einstein	USA	November 1978	April 1981	Pointed, imaging x-ray telescope, Bragg crystal, transmission gratings
Hakucho	Japan	February 1979	April 1985	Scanning, RMCs
Tenma	Japan	February 1983	∼1985	Gas scintillation proportional counter (GSPC), all-sky monitor
EXOSAT	ESA	May 1983	April 1986	Pointed, imaging x-ray telescope, large proportional counters, GSPC
Ginga	Japan–UK	February 1987	October 1991	Pointed, proportional counters
Kvant	USSR–UK–Netherlands–Germany	June 1987	–	Pointed, GSPC, coded mask, scintillation counter
Granat	USSR–Russia	December 1989	August 1999	Pointed, coded masks, all-sky monitor
ROSAT	Germany–UK–USA	June 1990	December 1998	Scanning, pointed imaging x-ray and EUV telescopes
ASCA	Japan–USA	February 1993	–	Pointed, imaging x-ray telescopes, imaging GSPC
RXTE	USA	December 1995		Pointed, large proportional counters, scintillation counters, all-sky monitors
BeppoSAX	Italy–Netherlands	April 1996		Pointed imaging x-ray telescope, coded mask, scintillation counter
Chandra	USA	June 1999		Pointed imaging x-ray telescope, spectrometers
XMM-Newton	ESA	December 1999		Pointed imaging x-ray telescope, spectrometers

and so far only LMXB showing both persistent pulsations and bursts. BeppoSAX is an Italian–Dutch satellite with instruments covering a wide energy band (0.1–200 keV). By discovering the x-ray afterglows of gamma-ray bursts it pointed the way to the solution of an old puzzle, the physical nature of gamma-ray bursts.

Highlights from ROSAT and ASCA

ROSAT and ASCA have complementary properties. ROSAT carries a large x-ray telescope with a position-sensitive proportional counter (PSPC) providing moderate spectral resolution (∼40%) in the 0.1–2.4 keV band. With its High Resolution Imager (HRI), a microchannel plate detector 'black-and-white' images with 5 arcsec resolution can be taken. The telescopes of ASCA cover the energy band 0.5–10 keV with CCD detectors and imaging gas scintillation proportional counters having superior energy resolution (∼20%), but worse angular resolution (∼3 arcmin), compared with ROSAT. Both satellites have been used by many astrophysicists to study a wide variety of problems. The numbers of scientific publications resulting from ROSAT and ASCA run to about 4000 and 1600, respectively, covering almost all fields of astrophysics. In the following a few highlights are presented.

ROSAT took the first x-ray picture ever of the MOON (figure 2(*a*)). The Sun-lit side of the Moon contains a uniform brightness distribution as in optical light. This is due to solar coronal x-rays undergoing Thomson scattering in a very thin layer of the lunar surface. The PSPC spectrum shows a broad spectral bump at 0.6 keV which is due to fluorescent resonance scattering by oxygen of the minerals of the lunar surface layers. The effective reflectivity of the Moon in the ROSAT band is only ∼0.01%; this means that the Moon behaves as a black body at x-ray energies. At the same time it casts a shadow on the 'diffuse' x-ray background (see later section). The small flux of x-rays apparently coming from the dark side of the Moon is probably produced in the Earth's upper atmosphere by charge-exchange processes of solar wind ions. This is the same mechanism which is responsible for the x-ray emission from cometary comas (see below).

COMETS are cold objects that have been described as dirty snowballs. Therefore the discovery with ROSAT of x-rays from COMET HYAKUTAKE on 27 March 1996 was surprising to many scientists (figure 2(*b*)). Later, another

four comets were found in the ROSAT All Sky Survey archive, including comet Levy. In total about a dozen comets have been detected by now in x-rays, mostly with ROSAT. Various physical processes have been proposed to explain the observed extended x-ray emission, including scattering of solar x-rays by cometary dust, x-rays produced by collisions of cometary and interplanetary dust particles and bremsstrahlung x-rays from electrons accelerated at the shock between the solar wind and the coma. However, all these mechanisms fail to explain the observed characteristics. The most successful and widely accepted model suggests that charge exchange between highly charged ions (such as C^{5+}, C^{6+}, O^{6+} and O^{7+}) in the solar wind and neutral particles (such as water) in the cometary coma is the dominant source of the observed x-ray emission.

ROSAT has given many exciting results about stars of all types. The study of a complete sample of stars of solar type has revealed the existence of a sharp lower bound to the x-ray flux, measured at the surface of the star. Interestingly, this minimum stellar x-ray flux is identical to the flux observed in the coronal holes of the Sun. This result suggests that the stars of minimal x-ray flux are completely surrounded by stellar analogs of solar coronal holes.

With ground-based optical follow-up observations of unidentified ROSAT All-Sky Survey sources, several hundred new T TAURI STARS have been identified based on Hα emission of hydrogen and lithium absorption. Surprisingly, many new T Tauri stars have been found far outside regions of ongoing star formation. Such 'off-cloud' T Tauri stars must have been either ejected from their birthplaces in the clouds with high velocities or formed in small cloudlets which have largely dispersed since then.

Recently, deep ROSAT observations have led to the discovery of young ($<10^6$ yr) brown dwarfs showing x-ray emission. The x-ray properties of these brown dwarfs, in particular their x-ray to optical light ratio, are similar to those of nuclear burning stars of low mass. This may suggest that young brown dwarfs have hot coronae responsible for the x-ray emission just like nuclear burning stars of low mass.

Early in the ROSAT mission a number of objects were discovered emitting extremely soft x-rays. They are very luminous and show temperatures of a few hundred thousand kelvins. It turned out that these sources are a species which had been predicted to exist but which had not been found before. They are WHITE DWARFS in binary systems accreting matter from their companions at a rate just sufficient to sustain steady nuclear burning on the surface of the white dwarf. Thus, they represent a unique situation in which steady nuclear burning is observed at the surface of a compact star.

Massive stars explode giving rise to a supernova when the nuclear fuel in their cores is exhausted. The core collapses to a neutron star or a black hole while the shell of the star is expelled in a giant explosion. A large fraction of the kinetic energy is converted by shocks into high-temperature x-ray emitting plasmas. Supernova 1987A was ROSAT's first-light target on 16 June 1990, but it turned out to be too faint to be seen at that time. Its remnant was first discovered in soft x-rays with ROSAT in 1992 and has steadily become brighter since then. A large increase is expected to occur in the near future when the shock reaches the high-density regions of the red giant wind. In total, some 200 supernova remnants have been found with ROSAT. Three of them are clustered in the Vela region (figure 3). One is the VELA SUPERNOVA REMNANT, which, at a distance of 1500 ly, is one of the closest supernova remnants. Its diameter is about 200 ly, its age about 20 000 yr. Protrusions discovered with ROSAT at the periphery of the shell are probably produced by fragments of the exploding star; x-ray spectroscopy with ASCA has revealed that they show different chemical compositions (figure 3(*a*)). The Puppis A remnant at the north-western rim of the Vela supernova remnant

Figure 3. The Vela complex of supernova remnants: (*a*) Vela supernova remnant with the Vela pulsar and Puppis A; (*b*) Puppis A with its central source, probably the remnant neutron star; (*c*) A young, ∼680 yr old supernova remnant, superimposed on Vela supernova remnant, showing titanium-44 emission. **This figure is reproduced as Color Plate 62.**

is located at a much larger distance (figure 3(*b*)). It is younger and has a much higher temperature than the Vela supernova remnant. Surprisingly, a third supernova remnant has been discovered recently in the Vela complex with ROSAT. Radioactive titanium-44 has been detected from it with the Compton Gamma-Ray Observatory (figure 3(*c*)). Titanium-44 is produced in supernova explosions and has a mean lifetime of only 90 yr, which means that the remnant is very young (∼680 yr). Actually, this supernova remnant looks like a twin of SN 1006. Like the latter it must have been very bright at maximum (about a quarter of the full Moon) and it is unclear why it has not been recorded in the Chinese and Japanese annals.

Neutron stars shine in different ways. If they are highly magnetized and rapidly rotating, they appear as radio PULSARS. These objects emit beamed radiation produced by high-energy electrons (and positrons) that are accelerated in their magnetospheres. In about half a dozen young pulsars, optical and gamma-ray pulses have also been seen. With ROSAT and ASCA, 34 radio pulsars have been detected through their magnetospheric x-ray emission, including the 89 ms Vela pulsar. The characteristic features of this magnetospheric radiation are power law spectra and sharp pulses. Four of the radio pulsars seen with ROSAT, including the Vela pulsar, exhibit an additional thermal spectrum corresponding to a temperature of the order of 10^6 K, which is interpreted as the thermal radiation from the surface (photosphere) of the neutron star. A few point sources discovered near the centers of young supernova remnants also show very soft x-ray emission, which must be attributed to neutron star surface emission as well. A prominent example is the central source in Puppis A (figure 3(*b*)).

Since the ages of radio pulsars and supernova remnants can be determined quite well, one can use these observations to test cooling models of neutron stars. The result is that standard cooling models describe the observed temperatures and luminosities quite well. Rapid cooling as expected in the presence of a Bose–Einstein condensate of pions or kaons in the neutron star core can be excluded for the observed objects.

A few x-ray sources have been found in the ROSAT data showing very soft thermal spectra, (temperatures below a million kelvins) and very faint optical counterparts (25^m–26^m). These objects might be either single neutron stars accreting interstellar matter or, more likely, old (10^5–10^6 yr) cooling neutron stars whose supernova remnants have already vanished. The importance of all these observations lies in the fact that the surfaces of these tiny stars (with radii 10 km) have now become visible. Future x-ray spectroscopy should make it possible to measure their enormous gravity as well as their radii, which depend on the physical properties of matter at supranuclear densities.

The ROSAT deep survey of the Andromeda galaxy led to the discovery of 550 x-ray sources, comparable in number with the bright x-ray sources in our own galaxy found by Uhuru. As in the Milky Way, the brightest of them are young supernova remnants or binary systems with neutron stars or black holes accreting matter from a companion. These bright source populations have been studied with ROSAT in many galaxies. In addition, the hot interstellar medium, which is heated by supernova explosions, has been investigated.

A small fraction of all galaxies have an ACTIVE GALACTIC NUCLEUS (AGN) emitting huge amounts of energy in all spectral bands. The radiation is variable, indicating that it is emitted from a small region, generally not more than a few light-weeks or light-months across. Such AGNs often display jets, originating in their core. It is generally believed that the central engine is a supermassive black hole swallowing matter at a high rate. QUASARS are the most extreme representatives of the class of AGN sources. ASCA spectroscopy of the AGN MCG-6-30-15 and a few other sources has led to the discovery of iron Kα emission lines with broad and asymmetric profiles. This profile is most probably caused by gravitational and relativistic Doppler shifts of the rapidly rotating matter in the accretion disk near the central black hole. These AGNs are very bright x-ray sources, and more than 50% of all 150 000 ROSAT sources belong to this class. Because of their enormous brightness, they can be detected at large distances or redshifts. In the ROSAT Deep Surveys with a total accumulated observation time of 2 weeks, about 1000 sources are detected per square degree in the sky. Optical spectroscopy has shown that most of them are quasars and other AGNs at cosmological distances. The ROSAT Deep Surveys have also answered one of the oldest questions of x-ray astronomy, namely the origin of the extragalactic x-ray background: at least, in the soft x-ray band, around 1 keV, some 80% of the background has been resolved into discrete sources, mostly quasars. An important current question is what evolved first, the galaxies or the supermassive black holes.

Galaxies are not distributed randomly in the universe but form clusters or groups of galaxies consisting of a dozen to thousands of members which are gravitationally bound. With diameters of millions of light-years, they are the largest physical objects in the universe. As early as 1932, Fritz Zwicky found that CLUSTERS OF GALAXIES must

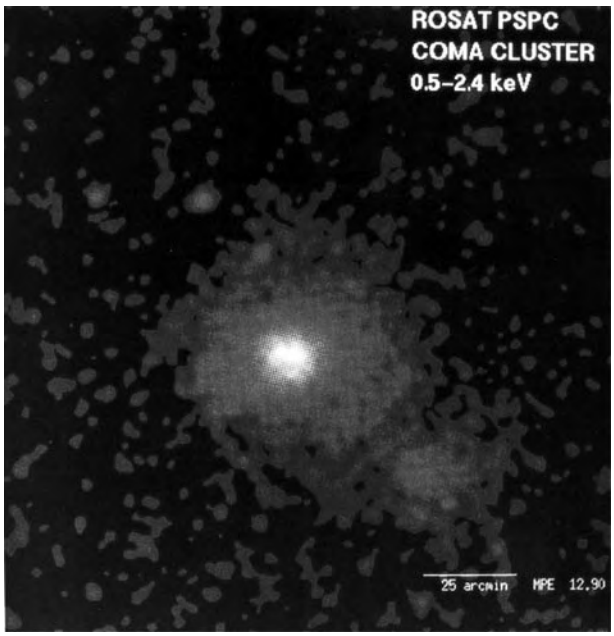

Figure 4. X-ray image of the coma cluster showing the merging with a smaller cluster of galaxies.

contain much more gravitating mass than accounted by the total visible mass of all member galaxies. Actually, the amount of 'DARK MATTER' had to be of the order of 95% of the total cluster mass.

One early surprise of x-ray astronomy was the detection by Uhuru of large quantities of hot plasma in clusters of galaxies shining in x-rays. Later Einstein and ROSAT observations showed that the mass of the hot plasma is typically a factor of 4 or 5 larger than that of the galaxies and represents some 20% of the cluster mass. In other words, a large fraction of the 'dark matter' turned out to be hot, visible only in x-rays and not in optical light. ASCA spectroscopy has allowed us to measure the heavy element (iron) abundance of the hot matter in clusters, which is typically only one-third of the so-called universal abundance. This can be explained by the infall of primordial matter onto the clusters.

Many clusters show double structures, indicating the merging of two clusters; others exhibit complicated inner structures which must be due to earlier merging processes (figure 4). Thus, the x-ray images reveal how these large objects evolve with cosmic time.

In total, several thousand clusters have been found with ROSAT. About 1500 of them have been optically identified and have known redshifts, and thus known distances. From this information one can derive the evolution of the cluster population with time. A comparison with simulations shows that the observed time dependence of the cluster population is significantly smaller than expected in a universe having the critical density. Actually the matter density inferred from cluster evolution is only about one-third of this critical density which is necessary to close the universe.

The future

During the years to come enormous progress is expected in x-ray astronomy owing to two new very powerful and complementary x-ray telescope missions: CHANDRA and XMM-NEWTON. Both satellites carry x-ray CCD detectors and dispersive spectrometers for high-resolution spectroscopy. The special strength of Chandra, launched in summer 1999, is its high angular resolution (∼0.5 arcsec) which allows us to resolve fine structures such as jets and to go at least a factor of 1000 deeper than the ROSAT deep surveys did. On the other hand XMM-Newton, launched in December 1999, provides a very high collecting power (∼4–10 times that of Chandra, depending on energy) at moderate angular resolution (∼10 arcsec). It will be very powerful for spectroscopic and time variability studies. The first results of these two powerful missions are very tantalizing.

Plans for the future thereafter are already quite concrete. NASA is discussing a fleet of four x-ray telescope satellites called 'Constellation' to be launched in ∼2007. They can observe the same object with different instruments simultaneously or point to different regions of the sky. ESA's XEUS (x-ray mission for spectroscopy in an evolving universe), to be launched after 2010, foresees a giant x-ray telescope with a huge mirror system and focal instruments sitting on two separate satellites, which means that pointing requires orbital maneuvers. The collecting area of the telescope (∼30 m^2) is a thousand times that of ROSAT and about a hundred times that of XMM or RXTE. It should be able to penetrate into the 'dark ages' of our universe at redshifts of 5–10, where galaxies and supermassive black holes have been formed.

X-ray Binary Stars

X-ray binary stars are luminous ($\sim 10^{36-38}$ erg s^{-1}) x-ray sources that consist of a neutron star or black hole compact object accreting material from a close (usually $\leq 1 R_\odot$) orbiting companion star which, in most cases, has properties similar to those of normal main sequence stars. Such x-ray binaries are rare (only ~200 are present in our Galaxy and are distributed in the Galactic Plane, the Galactic Bulge and a dozen or so as GLOBULAR CLUSTER X-RAY SOURCES, see figure 1), whereas the related (and in many respects similar) cataclysmic variables (where the compact object is a white dwarf) are much more common. The extremely high intrinsic luminosity of x-ray binaries (the brightest are at the 'Eddington Luminosity, a level at which radiation pressure limits the rate at which matter can accrete' for a $1 M_\odot$ star) accounts for their discovery in the early days of x-ray astronomy (via rocket-based experiments in the 1960s) and their domination of the field for most of the next two decades.

X-ray binaries can be divided into two basic classes of objects according to the mass of the mass-losing (or donor) star. The division is remarkably clean with those $\geq 5 M_\odot$ classified as 'high mass x-ray binaries' (HMXBs) and those $\leq 1 M\odot$ as 'low mass x-ray binaries' (LMXBs). The nature of the mass transfer from the donor also divides between these classes, with the (radiation driven) stellar wind dominating in HMXBs and Roche-lobe overflow being the principal mechanism in LMXBs (although there are circumstances in which a combination of the two can occur). The x-ray characteristics also depend on the nature of the compact object. High magnetic field neutron stars produce x-ray pulsators, whereas lower magnetic fields make it much harder to detect the spin of the neutron star, although 'x-ray bursts' can occur. Note that coherent pulsations and bursts are never seen in black hole systems.

X-ray binaries are extremely important objects as they demonstrate that stellar and binary evolution can produce compact objects via supernova explosions in which the binary survives. They currently provide the only circumstance in which stellar-mass black hole masses can be derived within our Galaxy (see BLACK HOLE CANDIDATES IN X-RAY BINARIES) as well as a majority of the accurately known neutron star masses. They are also a well-defined and constrained laboratory for studying accretion onto highly degenerate matter and the effect of ultra-high magnetic fields, and for testing the effects of general relativity in the strong gravity limit.

High mass x-ray binaries

X-ray pulsars

The very first x-ray astronomy satellite, UHURU, discovered X-ray pulsations at 4.8 s and 1.2 s in Cen X-3 and Her X-1, respectively, and also found that those pulsations were modulated (and eclipsed) on their orbital periods of 2.1 d and 1.7 d (see figure 2). These results immediately established the binary star model for these sources beyond any doubt. In combination with optical spectroscopy of the donor star (relatively bright, early-type stars for both sources), and the fact that they are eclipsing, they allow full orbital solutions and hence accurate masses for both donor and compact object (see table 1). Furthermore the duration of the eclipse provides an accurate estimate of the size of the donor which can be compared with the size of its Roche lobe.

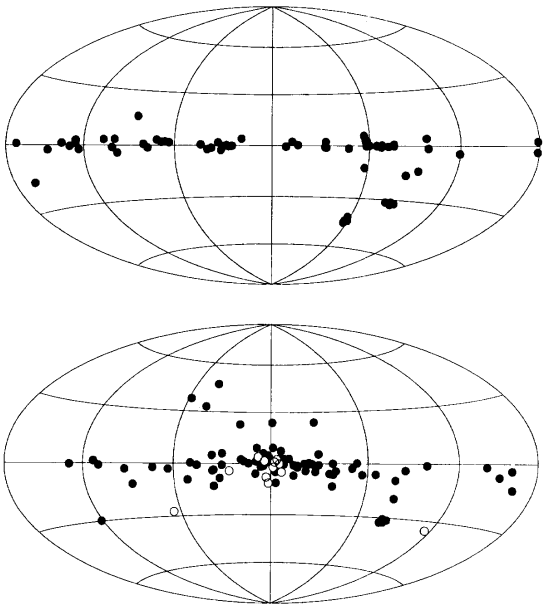

Figure 1. Distribution of x-ray binaries in the Galaxy. Top: HMXBs, associated with young, massive stars in the spiral arms. Bottom: LMXBs, an older population concentrated in the Galactic Bulge (also including globular clusters as open symbols).

Spinning up and down

The spinning neutron stars are orbiting their massive companions and accreting material from the dense and (presumed) uniform stellar winds. This physical situation is essentially identical to Bondi–Hoyle accretion as calculated for a single object moving and accreting from a uniform interstellar medium. Matter is accreted onto the neutron star from within a cylinder of radius $r_{\rm acc}$, defined as the point at which the kinetic energy of matter in the wind is equal to the potential energy due to the neutron star. If the wind's velocity is $v_{\rm w}$, and the orbital velocity of the neutron star is v then the fraction accreted is given by $(M_{\rm ns}/M_{\rm sec})^2 (v/v_{\rm w})^4 [1 + (v/v_{\rm w})^2]^{-3/2}$ and is usually $\sim 10^{-3}$ to 10^{-5} for typical HMXBs.

The angular momentum of this material will cause it to form a small accretion disk around the compact object, but its final capture by the neutron star is controlled by the intense magnetic field at the *magnetospheric radius* where the ram pressure of the (presumed spherical) infall is balanced by magnetic pressure. At this point the accreting angular momentum is transferred to the spinning pulsar, which then spins up at a rate $\dot{P}$ that is broadly proportional

LMC X-4	13.5	1.41	9.86	0.006	65	1.5	15.8
Vela X-1	283	8.96	19.74	0.09	>74	1.9	23.5
4U1538-52	530	3.73	11.8	<0.06	68	1.1	16.4

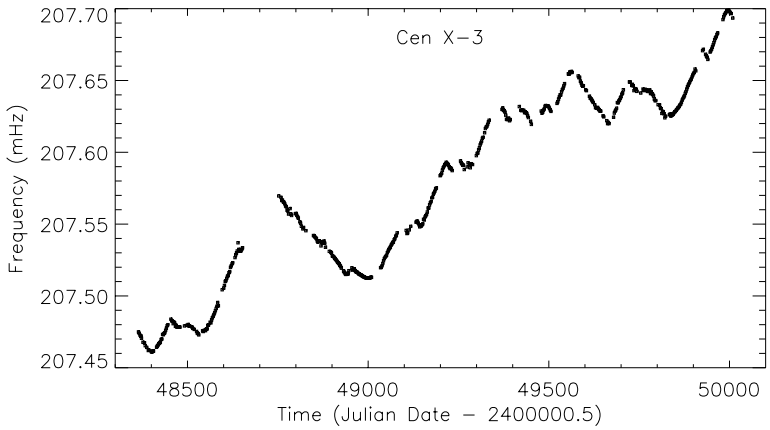

Figure 3. Approximately five-year history of the variations in the spin rate of the Cen X-3 pulsar as monitored by BATSE on CGRO. The general trend shows that on average it is spinning up, but there are significant fluctuations about this trend indicating that it can spin down as well as up.

to the observed x-ray luminosity (since this is directly related to the accretion rate).

Figure 3 shows the variation of spin period in Cen X-3 as observed by CGRO over almost five years. While the general trend is a spin-up, it is clear that the actual process involves periods of (almost equal) spin-up and spin-down. It might be expected that the spin-up rate would decline with x-ray luminosity if the mass transfer rate were to decline, but how does it manage to reverse sign? This requires that material is being accreted whose torque is reversed with respect to the 'normal' expectation, and implies that the disk rotation itself has reversed. Details of this process are unclear, but could be due to non-uniformities in the stellar wind.

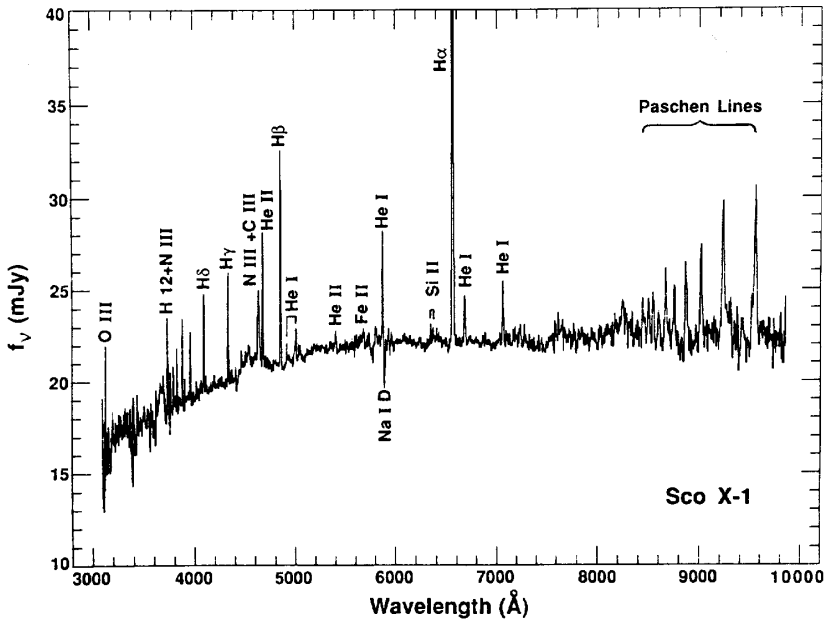

Figure 4. Optical spectrum of Sco X-1 which is dominated by continuum from the disk and x-ray driven high-ionization emission lines.

Table 2. Be x-ray binary parameters.

Source	Spectral type	V	Spin period (s)	Orbital period (d)	e	L_X(peak) (erg s^{-1})
A0538-66	B2IIIe	15	0.069	16.65	∼0.7	10^{39}
4U0115+63	OBe	15.5	3.6	24.3	0.34	8×10^{36}
V0332+53	Be	15.3	4.4	34.25	0.31	10^{38}
A0535+26	O9.7IIIe	9	104	111	∼0.3	2×10^{37}
GX304-1	B2Ve	14	272	133	?	3×10^{36}
4U1154-61	B1Vpe	9	292	188	?	10^{36}
X Per	O9.5ep	6	835	∼580	?	10^{34}

Note also that spin-up will only continue until the neutron star is rotating so fast that material at the magnetospheric radius would have to exceed the Keplerian speed at this radius in order to enter the magnetosphere (and hence would be ejected). Thus a magnetospheric 'barrier' then exists to counter any further accretion until either the neutron star has spun down or the mass transfer rate significantly increases.

Cyclotron lines

The magnetic fields of neutron stars that are x-ray pulsars are inferred to be $\sim 10^{12}$ G. Such fields control the accretion of material onto the neutron star's surface, leading to well-defined hot spots. x-rays are emitted either from the hot spot or from a shock immediately above the surface (within $\sim 10^{2-3}$ m), producing either pencil-beam or fan-beam emitting patterns. The very strong field will then lead to quantization of the energy levels within the accretion column, which produces resonant scattering cross sections and hence cyclotron emission and absorption features. In fact, cyclotron emission lines have only been seen in magnetic white dwarfs in the infrared, whereas cyclotron absorption features (most in the ∼12–40 keV range) have been detected in a dozen x-ray pulsars, implying magnetic fields of ~ 2–3×10^{12} G.

Be star transients

Many of the x-ray pulsars have long orbital periods with B-type companions which exhibit emission lines. These represent a sub-class of HMXBs and are associated with the rapidly rotating Be stars, so-called because of their strong and variable emission lines (usually hydrogen) superposed on otherwise normal B star spectra. A number of transient x-ray sources (most of them x-ray pulsators) have been identified with Be stars, establishing that both single and binary Be systems exist. The Be transients have rare outbursts (∼ hundreds of days) and long orbital periods (many weeks). Some (e.g. A0535+26, GX304-1) have poorly determined orbital periods >100 d, even with the accurately determined x-ray pulsation.

The Be phenomenon is interpreted as being due to the presence of an equatorial ring around the B star as

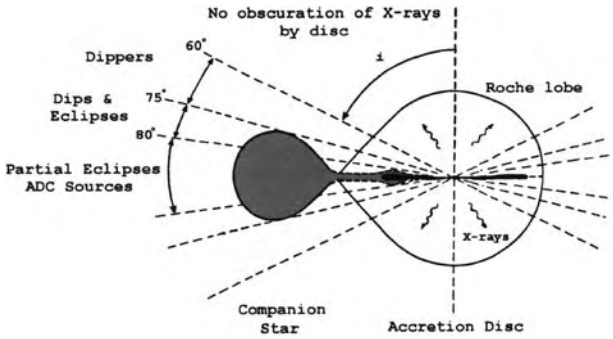

Figure 5. Schematic diagram of an LMXB showing the effects of disk shadowing and obscuration by the secondary star. Above an inclination of about 80°, LMXBs are seen only as ADC sources. Below about 75°, orbital modulation can still be seen in the form of regular dips, but these tend to evolve in form from cycle to cycle.

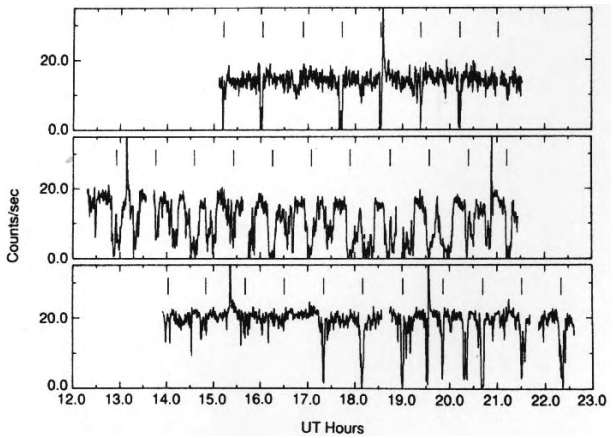

Figure 6. Continuous monitoring of X1916-053 by EXOSAT reveals both the regular x-ray 'dipping' due to azimuthal structure in the accretion disk, and the way in which this structure can evolve from orbit to orbit.

a result of its rapid rotation. Significant mass is lost via this ring and this material can be accreted by the orbiting neutron star, thereby producing x-rays. Almost all of the Be transients with measured orbits show significant orbital eccentricities (see table 2) and this may be related to the transient x-ray outbursts. An example here is A0538-66 in the LMC, which showed dramatic x-ray and optical outbursts on a 16.6 day cycle which was stable for at least 50 years (based on archival plate material), even though these outbursts did not always occur. At their peak these outbursts exceeded 10^{39} erg s^{-1} and yet the compact object was shown to be a neutron star based on an observed 69 ms pulsation. The most likely interpretation is that of a highly eccentric orbit ($e \sim 0.7$) in which the neutron star interacts (in a complex way) with the Be ring at periastron. Longer term (hundreds to thousands of days) variations are present in almost all Be systems, the nature of which is unclear. A recent extended (18 year) period of inactivity in A0538-66 has been attributed to the effect of the magnetospheric barrier given the very fast spin period of the neutron star. This could only be overcome by another interval of very high mass transfer from the secondary.

Low mass x-ray binaries

The brightest (and first discovered) extra-solar x-ray source is the x-ray binary Sco X-1, which was optically identified with an unremarkable 13th magnitude blue star in 1967. However, proof of its binary status was extremely hard to establish and this was not accomplished until the mid 1970s. This was due to the optical light being completely dominated by the x-ray heated accretion disk, making the secondary undetectable (see figure 4). Unlike HMXBs, the principal mass-transfer mechanism in LMXBs is Roche lobe overflow from the cool, low-mass secondary directly into the accretion disk. Furthermore, the thickness of the accretion disk itself can render a direct view of the compact object impossible at all phases (and not just when it is behind the secondary star), thereby making evidence for binarity less obvious than in HMXBs. This is demonstrated in figure 5 where the effect of shadowing by the disk leaves only a narrow range of viewing angles at which an orbital modulation can be seen. X-ray irradiation of the disk has been demonstrated in simultaneous multi-wavelength observations of X-RAY BURSTERS, which show the optical burst lagging the x-ray as a result of reprocessing of x-rays in the accretion disk and heated face of the companion.

A significant subset of LMXBs are globular cluster x-ray sources. Indeed, they are grossly over-represented in globular clusters when compared with the density of LMXBs in the Galaxy as a whole. Furthermore, all the globular cluster sources (see table 3) exhibit type I x-ray bursts, and recent HST studies of the extremely crowded UV/optical fields have revealed that several of these sources are ultracompact binaries with orbital periods $<$1 hour (including X1820-30 which has the shortest orbital period of any known object). It is likely that stellar interactions within the cluster core lead to the formation of such exotic objects.

X-ray dippers

A number of LMXBs display sudden 'dips' in their x-ray light curves which occur at particular orbital phases (around $\sim$0.8). These are attributed to extended vertical structure in the edge of the accretion disk at the point where the mass transfer stream impacts the disk. This material temporarily obscures our direct view of the x-ray source, absorbing the x-rays more effectively at lower x-ray energies (a signature of absorption which confirms the process). Extended observations of these x-ray dippers shows that the vertical disk structure evolves from orbit to orbit and on much longer timescales, sometimes disappearing altogether, at other times producing dip features throughout the orbital cycle (see figure 6).

J1744-28	283	Burster, pulsar, transient			0.47s pulsar, type II bursts

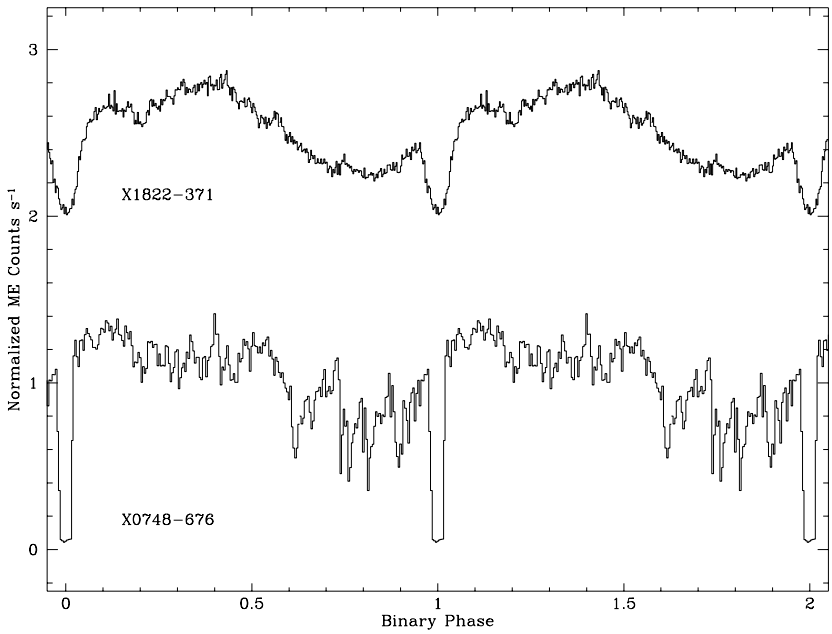

Figure 7. Comparison of the x-ray light curves of the prototype ADC source X1822-371 (top) with the eclipsing 'dipper' X0748-676. The orbital periods are very similar, but the orbital inclinations are only slightly different, with that of X0748-676 being just low enough to allow a direct view of the neutron star whilst still allowing the companion star to eclipse it (see also figure 5).

One particular source, EXO 0748-676, displays not only x-ray dips but also an (almost) total eclipse, albeit very brief (see figure 7). The inclination in this LMXB (a transient that turned on in 1985, and has remained 'on') must be in the very narrow range (73°–83°) that allows both dips and a short total eclipse by the secondary star.

Accretion disk coronae

However, a closer examination of figure 7 will show that the eclipse in EXO 0748-676 is not in fact completely total. There is a small but significant residual x-ray flux which is about 3% of the normal, out-of-eclipse level. This residual flux is due to x-rays which are scattered into our line of sight from material (possibly a disk 'wind') above and below the disk. Hence for sources at even higher inclinations, we would not expect to see total eclipses, but instead partial eclipses of this extended 'accretion disk corona' (or ADC). Figure 7 also shows the x-ray light curve of X1822-371, the classical ADC source which combines a long smooth modulation of the x-ray flux by the accretion disk rim structure with a partial eclipse by the secondary star. This is essentially what would be expected if the dipper light curve were to be smoothed out. ADC sources and x-ray dippers are important objects for the information that they provide on the azimuthal structure of accretion disks in interacting binaries.

X-ray pulsations

The much larger accretion discs in LMXBs compared to HMXBs should lead to substantial transfer of angular momentum onto the compact object and hence very fast spin periods (comparable to millisecond radio PULSARS). However, QUASIPERIODIC OSCILLATIONS IN X-RAY BINARIES were seen with large area x-ray detectors, an effect attributed to an interaction between the inner accretion disk and the neutron star magnetosphere. Very recently, the first millisecond x-ray pulsar was discovered (SAX J1808.4-3658) with a coherent pulsation at 401 Hz. It also displays x-ray bursts that indicate a weak ($<10^{10}$ G) magnetic field, and has a 2 h orbital period with a very low mass companion. This object is considered to be a direct link between LMXBs and the 'black widow' millisecond radio pulsars.

There is a further group, the 'anomalous x-ray pulsars' (AXPs), the nature of which remains very unclear. Only half a dozen are known, the best studied of which is 1E2259+587. They all exhibit coherent x-ray pulsations with periods in the range 5–12 s, have x-ray luminosities far too high to be explained by their observed spin-down rates and yet show no evidence for binary motion in these pulsations, nor has any been optically identified. It has been suggested that they may be linked to the 'soft gamma-ray repeaters' (a sub-class of gamma-ray bursters, see GAMMA-RAY ASTRONOMY) which also display similar pulsation periods during their bursts, an effect which led to the proposal that they had much larger magnetic fields than hitherto suspected (the so-called 'magnetars').

Long-term or superorbital modulations

From the early days of x-ray astronomy there have been satellites that scan the sky repeatedly and regularly (usually because they are spin-stabilized). This automatically provided the ability to monitor x-ray sources for many weeks (sometimes continuously), providing long-term light curves. These yielded the presence in a number of x-ray binaries, both LMXB and HMXB, of yet another modulation, this time quasi-periodic and on a timescale of tens to hundreds of days. The first discovered was the 35 d on–off cycle in HERCULES X-1, and which is attributed to a tilted, precessing disk. A similar ∼30 d modulation has been seen in LMC X-4, but a substantial change in this timescale over a year or so is difficult to account for. Subsequent long-term modulations (from 70 to 200 d) have been found in a variety of sources, including both LMXBs and HMXBs. These are currently attributed to the effects of a warped accretion disk driven by the central x-ray luminosity.

X-Ray Bursters

X-ray bursters are a class of sources which emit bursts of X-RAYS lasting from a few seconds to a few minutes. They are further classified as either type I or type II. Typical type I bursts have a faster rise than decay and the average energy of the x-rays decreases as the burst smoothly decays. Typical type II bursts stop abruptly without changing the average photon energy. There are now over 50 sources of type I x-ray bursts known, while only two sources are known as type II bursters, and one of these also has type I bursts. Because of this imbalance in numbers, 'x-ray burster' is assumed to mean a type I x-ray burster, although there are other kinds of sources of short bursts or flashes of x-rays, ranging from the Sun to black hole candidates. Type I bursters are NEUTRON STARS on which gas accreted from a binary companion undergoes sudden nuclear burning. The sources which have been called type II bursters are also neutron stars accreting gas from a binary companion. The type II burst is a sudden, large, but brief, increase in x-ray producing ACCRETION.

The neutron stars in x-ray bursters of both type I and type II have binary companion stars in close orbit such that the companion loses matter to the neutron star's gravitational attraction. (The companion fills the gravitational equipotential called the ROCHE LOBE.) The transferring matter has ANGULAR MOMENTUM around the neutron star, so that it circulates around it and mixes with gas already there in a flat ring distribution called an ACCRETION DISK. The disk material slowly moves inwards until it reaches the neutron star, where it accumulates on the surface. As helium and hydrogen accumulate under conditions of very high density and increasing temperature, the collisions of the ions can produce inelastic nuclear reactions which generate heat. The rising temperature increases the rate of collisions, raising the temperature further, until a nuclear fusion chain reaction is set off. This is the thermonuclear flash. The heat from burning the thin layer of helium, and sometimes hydrogen, diffuses out of the region. It heats the surface layers of the neutron star to a temperature at which x-rays are the dominant radiation emitted. Generally the radiation increases very quickly to its peak, sometimes in less than 1 s. The heat of the flash spreads to the surface and the burst decay corresponds to cooling of the surface.

From the burst x-rays and information about the distance or with assumptions about the peak brightness that the source can have, the radius and mass of the neutron star can be estimated. These values are close to those predicted for neutron stars and to the values measured in other ways, so that the conclusion that the star is compact enough to be a neutron star is firm. The measurements may eventually determine neutron star parameters, identify the composition of the matter falling on the neutron star and confirm ideas about the sequences of nuclear reactions that turn the accreted hydrogen and helium into the heavy elements of a neutron star's crust. The neutron stars have accreted angular momentum as well as mass. In some cases during the x-ray bursts the star is not uniformly hot and the flux has been found to be modulated with a period of 2–3 ms. These modulations are believed to indicate the spin of the neutron star and the characteristics of the modulation also provide information about the parameters of the neutron star. Thermonuclear bursts provide one of the few ways to obtain information about the densest matter.

Type I x-ray bursts

In 1975 there were three X-RAY ASTRONOMY satellites exploring the properties of sources found in the first x-ray survey mission, UHURU. Strong, short bursts of x-rays were first seen with the Astronomical Satellite of the Netherlands, then with SAS-3 and OSO-8, as sources in the region of the center of the Galaxy were observed. It turned out that the phenomenon had been seen as far back as 1969, by the Vela-5 satellites.

The sources from which the bursts appeared were in the direction of the bulge of the Galaxy, approximately 10 kpc away. From burst peak fluxes of 10^{-8} erg cm^{-2} s^{-1}, factors of 5–20 times normal or persistent flux of the sources, the peak luminosities are $\approx 10^{38}$ erg s^{-1}. This is close to the maximum luminosity possible for a $1M_{\odot}$ object, at which the radiation pressure due to photon scattering balances the force of gravity. (This 'Eddington limit' depends on the chemical abundances of the gas.)

The bursts were observed mostly in the photon energy range 1–20 keV. Generally they have a distribution with energy at a given time that is well approximated by a black body function with a temperature of $T \approx (1\text{–}4) \times 10^7$ K, corresponding to $kT \approx 1$–3 keV. Equating the estimated luminosity to the radiation rate from a spherical black body,

$$L_x = 4\pi R^2 \sigma T^4$$

the radius R can be estimated to be $\approx$10 km. This is consistent with the expected radius of a neutron star. It is one of the best pieces of evidence that the objects are neutron stars. Figure 1 contains schematics of the x-ray luminosity, temperature and apparent radius derived for a type I x-ray burst. The integral of the excess luminosity due to the burst is its fluence.

When a source is burst active, the bursts recur at intervals, usually of several hours to days, as illustrated in figure 2. The phenomenology points to a process in which the fuel builds up until it catastrophically ignites. The energy output is consistent with the nuclear burning of the accumulated matter. If the gravitational energy released in accretion is turned into x-ray flux $L_x = GM\dot{M}/R$, the mass accumulated in time T is

$$\Delta M = \frac{L_x}{GM/R} T.$$

Scaling to nominal observed values for L_x and T,

$$\Delta M \approx 10^{21} \frac{L_x}{10^{37}\ \text{erg s}^{-1}} \left(\frac{R}{10\ \text{km}} \Big/ \frac{M}{1.4 M_{\odot}} \right) \frac{T}{5\ \text{h}}\ \text{g}.$$

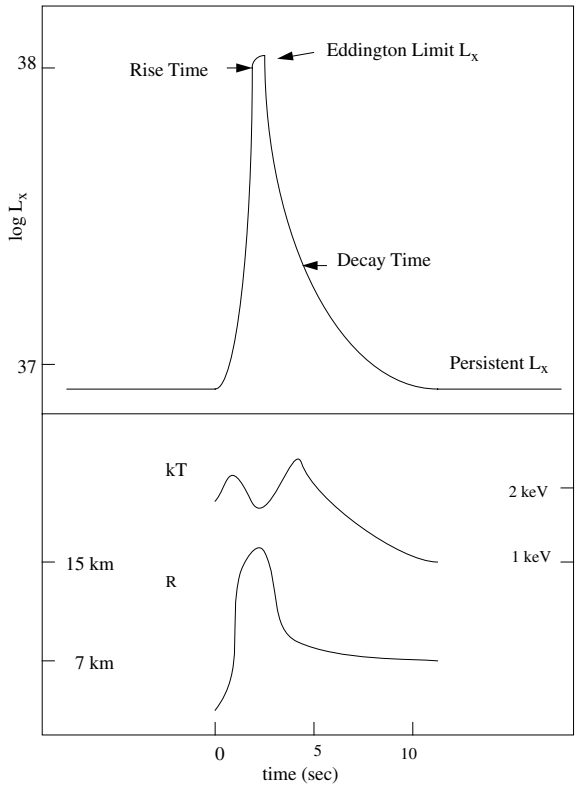

Figure 1. Type I burst parameters. The upper panel shows a schematic of the x-ray luminosity of a burst as a function of time. The lower panel shows a typical behavior of the fitted black body kT (right-hand scale) and the deduced apparent radius of a spherical emitter (left-hand scale).

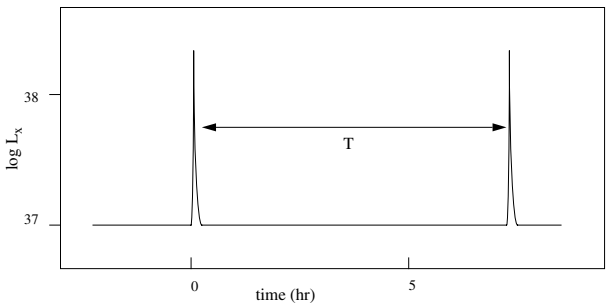

Figure 2. Persistent and burst luminosities. The average burst luminosity is the fluence in a burst per the recurrence time T.

There are a number of nuclear reaction sequences by which accreted material with the abundances of the outer layer of the companion star can convert into the iron and higher atomic number elements of the neutron star crust. The amount of energy released per nucleon is 2–8 MeV, so that the potential for energy release from burning, in the mass accumulated, is

$$\Delta E = (15\text{–}76) \times 10^{38} \times \frac{L_x}{10^{37}\ \mathrm{erg\ s^{-1}}} \left(\frac{R}{10\ \mathrm{km}} \Big/ \frac{M}{1.4 M_\odot} \right) \frac{T}{5\ \mathrm{hr}}\ \mathrm{erg}.$$

If the peak flux were the Eddington limit $2.0 \times 10^{38} M/1.4 M_\odot$ erg s^{-1} (assuming cosmic abundances here), it would take 7–40 s to cool the hot layer, with the heat convecting and diffusing to the surface in $\leq$1 s.

Generally, in the thermonuclear flash, the ratio of the persistent x-ray luminosity to the average burst luminosity (the fluence per burst divided by the recurrence interval) should be the ratio of the gravitational energy released per gram falling on the neutron star to the nuclear energy released in burning it. The observational quantity, denoted α, is equal to the ratio of the fluxes. The predicted values of α are in the range 25–200, depending on the nuclear reaction track. Some reaction tracks imply particular correlations between burst characteristics and the persistent luminosity. Theoretical calculations indicate that the nature of the reactions is more likely to go through cycles than to be a steady state, as the accretion rate changes and with it the ambient temperature of the settling material. The general agreement is regarded as a strong confirmation of the thermonuclear flash model of type I bursts.

Type II x-ray bursts

Type II x-ray bursts usually (but not invariably) have the ratio of persistent luminosity to burst luminosity (α) too small to be consistent with what is known about thermonuclear reactions, well below 25. The first and recurrent example of this type is MXB 1730 − 335, appropriately called the Rapid Burster. The source becomes bright approximately every 6 months and for a few weeks goes through several metamorphoses of behavior, sometimes exhibiting rapid-fire bursts a few minutes apart. The Rapid Burster is also a source of type I bursts, so that the two different types of bursts can be compared for the same source. The second source was the transient GRO J1744 − 28, which first became known in 1995 as the Bursting Pulsar. This transient has reappeared once, so that it is recurrent, although irregularly. Bursts typically came about 30 min apart when it was active.

An increase in the rate at which matter falls on the neutron star can explain these bursts. Several possible mechanisms have been identified to store up the matter coming in, at some distance from the neutron star, and to release it suddenly to complete its journey to the neutron star.

The matter in accretion disks works its way to smaller radii as viscous interaction with neighboring cells of the accretion disk removes its angular momentum. As matter is continuously fed into the disk by the companion star, the viscous properties change and a sudden transition can occur from a state of low viscosity to high viscosity. The higher torques allow matter to start moving rapidly through the disk. The emission that we see as the burst can come both from the disk itself and from the neutron star where the matter falls on it. This instability can operate on

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

a range of recurrence time-scales, from years to minutes, so that it could give rise to bursts as well as to dwarf and x-ray NOVAE.

A different possible cause of the intermittent flow onto the neutron star is the interaction of the neutron star's magnetic field with the matter approaching the star. The magnetic field of the neutron star, if strong enough, interacts with the inner accretion disk. In the case of strong field PULSARS at some radius the field channels the disk material out of the plane and along the magnetic field lines to the magnetic poles. For the case of weaker fields, the disk may interact with the field over an extended region. It has been suggested that material could accumulate outside the magnetosphere until some threshold condition occurred that would allow the material to suddenly feed onto the neutron star.

For the Bursting Pulsar, pulsations with a period of 0.5 s continued throughout the bursts. Considerations of how low the accretion rate can go before pulsations cannot occur have allowed the surface magnetic field to be estimated at 5×10^{11} G. The Rapid Burster is likely to have a field weaker by several orders of magnitude and possibly the two sources represent two different instability mechanisms.

Thermonuclear flashes

Hydrogen and helium burning

As the accreted material collects on the neutron star, it will spread out over the surface if the magnetic field is too weak to confine the plasma (below 10^{11} G). If the companion is still on the main sequence, the material is, by weight, 70% hydrogen, 30% helium, with no more than a few per cent in heavier elements (C, N, O). However, in at least one case, 4U 1820−30, the companion is known to be a helium WHITE DWARF. When there is a layer of $\approx 10^{21}$ g on the surface of the neutron star, the density at the bottom of the accreting layer reaches $\approx 10^5$ g cm^{-3}. Nuclear reactions begin to convert hydrogen into helium and helium to oxygen. These reactions release heat. At very low and very high rates the heat can be radiated as fast as the energy is released and the hydrogen burning is stable, but under many conditions the burning is unstable, and the temperature increases rapidly until the fuel is completely burned. Helium burns by the triple-alpha reaction $3\alpha \rightarrow {}^{12}\mathrm{C}$ and by ${}^{12}\mathrm{C}(\alpha, \gamma){}^{16}\mathrm{O}$, usually unstably. Detailed calculations have examined the kind of succession of bursts that should occur, for a range of accretion rates, central neutron star temperatures and neutron star masses and radii.

Observed and modeled burst properties

For the intermediate accretion rates at which instabilities occur, three regimes have been distinguished. Helium burns unstably but, depending on the accretion rate, hydrogen, if present, may burn stably or unstably. In the middle of these three regimes the hydrogen burns stably (unless the interior temperature is very hot) and produces helium which flashes with $\alpha \geq 100$, recurrence times $\geq$10 h, and burst rise times $\leq$1 s. At either higher or lower accretion rates, the hydrogen and helium burn together, with complex reactions, building to iron and heavier elements. These reactions give the burst a longer rise time and can leave unburned fuel, so that the thermonuclear luminosities, and therefore the values of α, are lower.

Type I bursts from different sources are observed to be similar, but not identical. Bursts rise times range from 0.3 to 10 s and decay times range from 5 to 100 s. The decay times (τ) and the values of α vary with the persistent luminosity. The EXOSAT Observatory caught several sources in different states. Comparison of the behavior of the parameters with the predictions of models has led to investigations of other degrees of freedom, for example, dependence of the internal temperature on the history of the burning and the extent of the burning area on the neutron star.

For many of the x-ray bursters the persistent luminosities vary, sometimes consistently, but not exactly periodically. Some are transient persistent sources in which accretion may hardly occur in between episodes years apart. Then they rise to maximum in hours and decay over several weeks to a year. The sources 4U 1608−52 and Aquila X-1 are regularly recurrent transients. As the persistent flux may vary by factors of a thousand and the supply of mass to the neutron star envelope is believed to vary accordingly, the integrated effect must be considered.

Radius expansion during bursts

As the temperature during bursts rises and falls, the projected area of the hot emitter can be tracked. For many burst measurements the size of the emitter has been consistent with it remaining approximately constant throughout the burst. For a subset of bursts the apparent size increases near the beginning of the burst to values as much as 10 times sizes theoretically estimated for neutron stars. The apparent size then drops back and levels off at an asymptotic value consistent with that of a neutron star (as in figure 1). In these cases the bolometric luminosity stays approximately constant during the expansion episode. The temperature goes down during the expansion. The peak luminosity appears to be the Eddington limit for helium for most 'radius-expansion' bursts.

Theoretically, helium flashes can generate enough energy to cause photospheric expansion of the neutron star. When the surface luminosity reaches the Eddington limit, it drives a wind from the neutron star. There is evidence within bursts from a single source that some reach a plateau of luminosity $\approx$1.7 times lower than the radius-expansion plateau luminosity of others. This has been interpreted as the Eddington limit for hydrogen-rich gas, a factor 1.7 below that of helium. These characteristics can be identified from the spectra, without knowing the distance of the source, and are used as the basis for estimates of the distances to some burst sources. In the cases in which a distance is known on other grounds, they are in approximate agreement.

General relativity corrections and radiation transfer

The assumptions of black body emission and Eddington-limited flux seem to offer the possibility of measuring the radii and masses of neutron stars. These are interesting because they depend on the properties of the matter at densities of 10^{15} g cm^{-3} at the center of the neutron star. At least seven of the type I bursters are in GLOBULAR CLUSTERS and some of their distances are known to within 10%. However, several important effects must be included in interpreting the measurements. For neutron stars, the corrections of general relativity can be important; for a nominal $1.4M_\odot$ star, the Schwarzschild radius is 40% of the nominal radius of 10 km and the relativistic effects can be larger for some equations of state. Further, the surface temperature of the neutron star exceeds 10^7 K and the neutron star has a scattering atmosphere. The surface has an energy-dependent emissivity. These effects need to be taken into account in understanding and using the observations to determine the neutron star parameters.

A spherical black body neutron star has an apparent radius larger than the radius at the star, because of the gravitational bending of rays. Taking this into account, with

$$1 + z_* = (1 - R_g/R_*)^{-1/2}$$

$$R_\infty = R_*(1 + z_*)$$

(as long as $R_* \geq (3\sqrt{3}/2)R_g$), where $R_g = 2GM/c^2$ is the Schwarzschild radius, R_* the real neutron star radius and R_∞ the apparent radius we measure, which exceeds the real radius. The Eddington limit for the luminosity as observed by a distant observer gives another constraint on M and R_*. Together with possible theoretical mass–radii relations the Eddington limit implies a limit on the 'effective' temperature (defined by $T_e = (L_x/4\pi R^2\sigma)^{1/4}$), such that kT_e should never exceed 2 keV. The black body fits determine a 'color' temperature T_c, which at its peak often exceeds this limit on the effective temperature. This is a measure of the error in the assumption of black body emission. When the competition between scattering and absorption, the temperature increase with depth in the atmosphere and incoherent scattering in the atmosphere are all included, the ratio T_c/T_e has been found to vary between 1.4 and 1.7 as the flux approached the Eddington-limited flux.

Detailed data for bursts have been obtained by x-ray experiments on many satellite missions, notably OSO-8, SAS-3, HEAO-1, EXOSAT, Tenma, Ginga, RXTE and BeppoSAX. Extensive work was done attempting to determine the properties of the neutron star using the EXOSAT and Tenma data. Measurement and perhaps systematic errors prevented definitive results from being obtained. Similar projects to examine RXTE observations, which have much smaller statistical error and higher time resolution, are still in progress.

The neutron stars

X-ray bursters are in very old BINARY SYSTEMS, as shown by the population in globular clusters. At least three may well have degenerate dwarf companions (4U 1916 − 053, 4U 1820−30 and SAX J1808.4–3658) and all of the companions are low-mass stars. It has been suggested that in accreting over 10^8–10^9 yr the neutron star's magnetic field has decayed. When radio pulsars with 10^8–10^{10} G fields were discovered with rotation periods of a few milliseconds, it was suggested that accretion in the low-mass x-ray binaries spins up the neutron stars to millisecond periods. Then irradiation could evaporate the companion, leaving a rejuvenated, millisecond, radio pulsar. Recent observations with RXTE discovered evidence tending to confirm this scenario. The transient and burster SAX J1808.4–3658 is now known to be an x-ray pulsar. It has a magnetic field estimated to be 5×10^8 G and a rotation frequency of 401 Hz (a period of 2.5 ms).

In six other bursters an inhomogeneity in temperature on the star appears during bursts and appears to rotate. The periods are similar to the period of SAX J1808.4–3658. At the beginnings of bursts a high-amplitude (as high as 60%) sinusoidal oscillation starts. The oscillation amplitude decays along with the rise in flux. This behavior would be consistent with a growing burning region. The periods are 1.7–3 ms. During the decays, 10 s trains of oscillations occur with typical amplitudes of 10%. Whether the asymmetry is associated with one spot or two is uncertain. Together with new and related results on fast quasi-periodic oscillations in the persistent flux, they provide new, and potentially precise, tools to determine properties such as the masses and radii of the neutron stars, their magnetic fields, the radii at which the disks terminate and how the accreting gas traverses from the disk to the neutron star. With RXTE, BeppoSAX, Chandra and XMM it will be possible to address many questions about x-ray bursters, the evolution of the systems, the flow of accreting gas, the progress of thermonuclear flashes and the neutron star solutions for collapsed stars of $\leq 3M_\odot$.

Bibliography

The literature on the subject of x-ray bursters includes a number of reviews, which are well represented in the chapters by

X-Ray Telescopes

X-ray telescopes produce images of x-ray-emitting objects within the telescope's FIELD OF VIEW by reflection from precisely shaped mirrors. Hans Wolter's design in the early 1950s of an x-ray microscope using reflective optics led Riccardo GIACCONI to suggest an 'inverted' set of optics, not subject to the fabrication limitations of the microscope, could be used as a cosmic x-ray telescope. As described in 1960 by Giacconi and Bruno ROSSI, imaging with x-ray telescopes offers a significant reduction in noise, both from cosmic ray induced events and the soft x-ray background. This is because most background counts are the result of charged particles and are uniformly distributed over the detector area. An imaging system concentrates the source counts in one or a few pixels. As an example, the EINSTEIN (HEAO-2) Observatory x-ray telescope offered an improvement in sensitivity of about a factor of 1000 over that of the large-area, collimated proportional counters on High Energy Astrophysical Observatory (HEAO) 1 satellite. The improved instrument sensitivity resulting from increased signal to noise enables the study of fainter sources, extending the number and age of detectable objects.

Imaging observations enable deeper study of extended cosmic x-ray sources. Imaging of CLUSTERS OF GALAXIES reveals details of the intracluster gas temperature profile and isolates the x-ray emission from component galaxies. Imaging of GALAXIES allows study of any central source as well as the identification and location of the galactic emitters. Study of SUPERNOVA REMNANTS allows the visualization of the x-ray-emitting regions and potential identification of a remnant's compact object. None of these types of studies is readily undertaken with non-imaging instruments. Other imaging approaches employing such devices as modulation collimators or scanned, tightly collimated detectors provide much poorer resolution (∼1 arcmin.) than that available with current x-ray telescopes and suffer from image reconstruction artifacts.

Studies of point sources also benefit from x-ray telescope resolution. Using the large-area proportional counters on board HEAO-1, positions accurate to ∼0.1 square degrees were obtained for weak point sources. On average, there will be one star brighter than 12th magnitude in the position error box. For comparison, the optical counterparts of Sco X-1 and Cen X-1 are about 13th magnitude, and that of Her X-1 about 15th magnitude. Imaging enables more accurate optical identifications. With better than 0.5 arcsec resolution of the Chandra X-ray Observatory (CXO) positions of point sources accurate to $\sim 10^{-7}$ square degrees may be obtained—on average less than a single unrelated 20th magnitude star will be found in the error box.

This article will first briefly discuss how x-rays may be reflected and what optical systems can be used to form images. Key considerations for performance and system design will be discussed, followed by the various ways of implementing x-ray telescopes. We will review the more significant past and current x-ray telescopes, and then discuss future trends in x-ray telescopes.

X-ray reflectance

X-rays specularly reflect from a surface under two conditions, when striking a surface at grazing incidence and when constructive interference takes place between many layers of a material whose atomic number varies in a periodic fashion.

Reflection at grazing incidence

At x-ray wavelengths the real part n_r of the complex index of refraction $n_r - ik$ of the reflecting surface is less than 1. Thus x-rays in vacuum are incident upon an interface that is less optically dense. From Snell's law the angle of the wave transmitted θ_t into the less dense material is

$$\sin\theta_t = (n_1/n_2)\sin\theta_i \tag{1}$$

where θ_i is the angle of incidence and n_1 and n_2 are the indices of refraction for vacuum and the reflecting material, respectively. When $n_1 > n_2$ one obtains a real value for θ_t only for incident angles $\theta_i < \sin^{-1}(n_2/n_1)$. For example, if $n_2 = 0.99$, then the maximum real value for θ_i is 81.9°: at this incident angle the transmitted angle is 90°, parallel to the interface. For larger incident angles (shallower grazing angles) no radiation is transmitted. This is seen by allowing θ_t to be complex, with

$$\cos\theta_t = \pm i[(n_1/n_2)^2\sin^2\theta_i - 1]^{1/2}. \tag{2}$$

Substituting equation (2) into the Fresnel equations, solving for the transmitted electric and magnetic fields, and determining the time-averaged Poynting vector reveals that no energy flows through the interface—the field intensities normal to the interface decay exponentially into the less optically dense surface.

Reflectance is calculated from the complex index of refraction using the Fresnel equations. The real and imaginary parts of the index are computed from the atomic (forward) scattering factors f_1 and f_2:

$$n_r = 1 - \delta = 1 - \frac{\rho}{W_m} A_0 r_e \lambda^2 f_1 \frac{1}{2\pi}$$

$$k = \frac{\rho}{W_m} A_0 r_e \lambda^2 f_2 \frac{1}{2\pi} \tag{3}$$

where ρ is the material density, W_m is the molar weight of the reflecting material, A_0 is Avogadro's number, r_e is the classical electron radius and λ is the incident wavelength. The scattering factors are material and wavelength dependent. They are derived in a variety of ways: they may be computed from measurement of the forward scattering amplitude or back calculated from measured x-ray reflectance. Well-known sets of constants have been published by Henke *et al*, Auerbach and Tirsell, and Windt. As better reflectance is achieved with materials with high electron density grazing incidence optics are typically coated with metals to enhance reflectance.

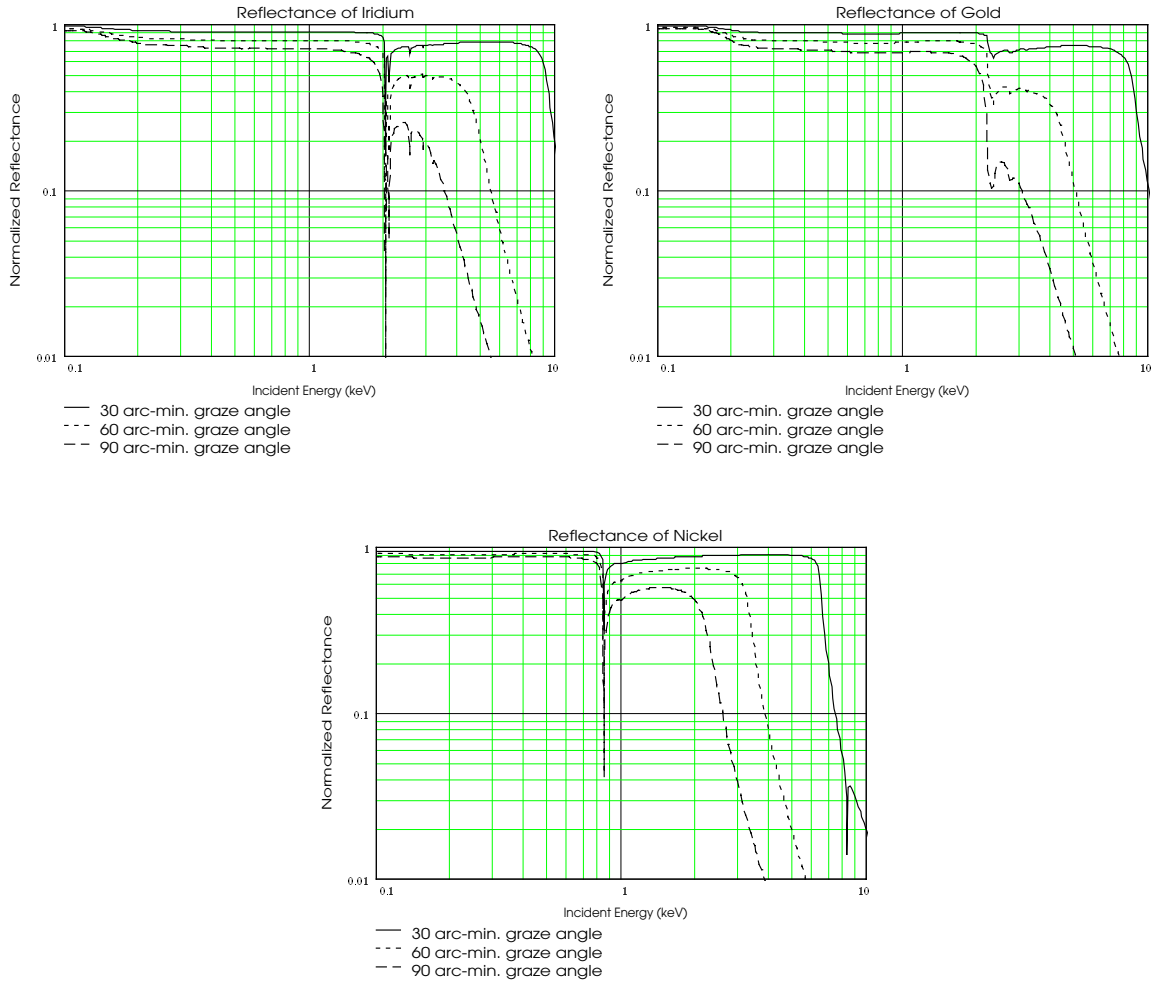

Figure 1. X-ray reflectance as a function of incident energy and graze angle.

Common materials used as reflecting coatings are iridium, gold and nickel. A plot of x-ray reflectance as a function of incident energy and grazing angle is shown in figure 1. Note the local minima in reflectance at the location of x-ray absorption edges. The product of reflectance and geometric collecting area (the entrance aperture) is called the effective area. Reflectance decreases as a function of increasing graze angle and starts to decrease rapidly near the so-called critical angle. The critical angle may be expresses as $\cos^{-1}(n_r) \approx (2\delta)^{1/2}$ for $\delta \ll 1$ (see equation (3)).

Reflection from multilayer coatings

Multilayer coatings contain alternating layers of high-Z (atomic number) and low-Z materials. Reflection occurs at each interface, and the layer optical thicknesses are chosen so as to produce constructive interference between each layer. Reflection occurs only for those wavelengths which satisfy the Bragg equation,

$$m\lambda = d \sin\theta \qquad (4)$$

where d is the layer spacing and θ is the incident angle. In practice the coating reflects a bandwidth $\Delta\lambda$ that is a function of various fabrication parameters including layer thickness uniformity, density, and layer materials but is typically only a few ångströms wide. Typical layer material pairs include (but are not limited to) nickel/carbon, tungsten/silicon, rhodium/beryllium, rhodium/carbon, molybdenum/carbon and platinum/carbon. A typical coating may contain between 40 and 500 layer pairs, with the larger number of layers yielding higher reflectance. Reflectance of 10–80% has been achieved, depending on the incident wavelength (higher reflectance at longer wavelengths) and material choices.

Several soft x-ray–EUV, normal incidence, multilayer telescopes have been launched on board sounding rockets and small satellites, including the recently launched Transition Region and Corona Explorer (TRACE). To overcome the spectral bandwidth limitations of multilayer coatings, experimenters have resorted to integrating several smaller telescopes into a single payload, each telescope with a different multilayer. In

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

the case of TRACE, different multilayer coatings were applied to each of the four quadrants of the optics so that a single telescope was sensitive to four separate spectral bandwidths (one of which was visible light).

An alternative to several different telescopes or multiple different coatings on a single telescope is graded multilayers, or 'supermirrors'. Here, the layer thickness varies as a function of position (depth) in the layer stack. The thickest layers are at the top of the stack to reflect the longest wavelengths with a minimum of absorption. Good broadband reflectance has been achieved using a thickness law

$$d_i = a(b+i)^{-c} \tag{5}$$

where d_i is the thickness of the ith layer (starting from the top), a and c are positive parameters that are a function of the materials used, and b is a constant greater than -1.

Substrate and coating roughness degrades multilayer performance. 'Low' frequency roughness ($>1\,\mu$m periods) causes scatter which degrades image contrast. 'High' frequency roughness ($<1\,\mu$m periods) reduces reflectance.

Types of telescopes

Two approaches are used to achieve imaging: grazing incidence (GI) and normal incidence (NI). Grazing incidence telescopes utilize large angles of incidence (near 90°) so that the x-rays graze or glance off the surface and are reflected. Normal incidence x-ray telescopes use more conventional shaped optics with multilayer coatings.

Grazing incidence telescopes

In 1952 the German physicist Hans Wolter was able to show that a two-element system containing an even number of confocal conic optics will come close to satisfying the Abbe sine condition; rays that reflect off both surfaces are focused and form an image. Wolter, attempting to produce systems for x-ray microscopy, produced three designs, referred to as Wolter types I, II and III. The type I telescope (figure 2) consists of a paraboloid as a primary mirror and a confocal and coaxial hyperboloid as the secondary mirror. The paraboloid focus is coincident with the back hyperboloid focus. X-rays strike the paraboloid at the grazing angle (approximately the field angle of the source plus half the angle subtended by the best-fit cone to the paraboloid), are reflected and strike the hyperbola. The image is formed at the front hyperboloid focus. Usually, the hyperboloid cone angle is three times that of the paraboloid so that on-axis x-rays are incident upon both mirrors with essentially the same grazing angle. X-rays that strike the forward end of the paraboloid reflect to strike the aft (back) end of the hyperboloid, and vice versa.

The entrance aperture is the projection of the primary mirror in the aperture plane. This results in an annular aperture whose width is approximately the product of the optic length and the half-angle of the best fit cone (the cone angle). For the CXO the largest paraboloid has a surface area of approximately 3.2 m^2 but an entrance aperture of only 0.047 m^2, a reduction of a factor of

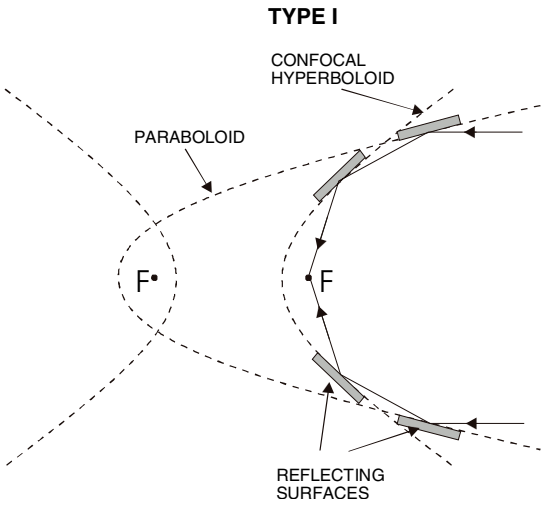

Figure 2. Schematic representation of the Wolter type I telescope.

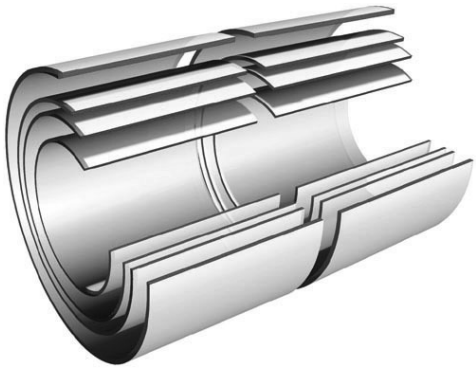

Figure 3. Cutaway schematic drawing of the nested four shells (paraboloid and hyperboloids) of the Chandra X-ray Observatory (courtesy of the Raytheon Co).

~68 times. Collecting area is built up by nesting mirror pairs within one another (figure 3). Each mirror pair, or shell, is co-aligned and confocal. The telescope entrance aperture consists of a set of concentric annular apertures, all contributing to the same focus. Ideally, the shells are designed so that each one has the same focal length and therefore the same plate scale (the proportionality constant relating angular distance on the sky to linear distance at the focal plane). All shells do not necessarily contribute the same to the image as a function of x-ray energy. As shown above in the section 'X-ray reflectance', reflectance is a function of graze angle and incident energy. The inner shells have a shallower graze angle than outer shells. Thus the inner shells of a nested telescope have a larger spectral bandwidth (reflect higher-energy x-rays) and comparable or slightly higher reflectance than the outer shells, while also having a smaller entrance aperture.

The type I design yields a perfect image for on-axis illumination. Off axis, the design suffers from field dependent coma and spherical aberration. In addition,

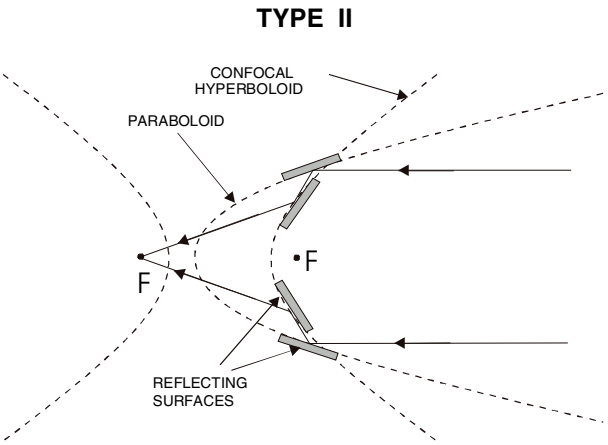

Figure 4. Schematic representation of the Wolter type II telescope.

the telescope focal surface is curved. Van Speybroeck and Chase (1972) approximated the off-axis rms blur diameter for a flat focal plane detector at the Gaussian focus as

$$\sigma_{\text{blur}} \approx 4\frac{\xi+1}{10}\frac{(\tan\theta_{\text{field}})^2}{\tan\alpha}\frac{L}{Z_0} + 8\tan(\theta_{\text{field}})(\tan\alpha)^2 \qquad (6)$$

where θ_{field} is the field angle (the off-axis angle), α is the graze angle, Z_0 is the axial distance from the intersection of the paraboloid and hyperboloid surfaces (the 'virtual joint') to best on-axis focus, and L is the axial length of the paraboloid. The first term in equation (6) represents the field-dependent coma. The second term is split between a GI equivalent of spherical aberration and image defocus (relative to a flat detector) due to a curved focal surface. For the Chandra X-ray Observatory at a field angle of 5 arcmin, the rms blur diameter ranges from 2.5 arcsec to 4 arcsec. Alternative Wolter I type designs exist that mitigate the off-axis aberrations at the expense of degrading on-axis performance. These designs consist of using two coaxial (but not confocal) hyperboloids or using generalized (non-conic) mirror prescriptions such as a power law. Because of the relative mechanical simplicity of the design and the ability to increase collecting area by nesting telescopes the type I design (or its variants) is the most common form of grazing incidence designs used in x-ray astronomy, being employed on the Einstein Observatory, Roentgen Satellite (ROSAT), CXO, X-ray Multi-mirror Mission (XMM) and many others described later.

The type II design also consists of a grazing incidence paraboloid primary and hyperboloid secondary mirror, but the outer surface of the hyperboloid is used, as shown in figure 4. In the type II the image is formed at the back hyperboloid focus. Type II telescopes enable longer focal lengths than a type I with comparable grazing angle and entrance aperture, affording an increased plate scale. Field-angle-dependent aberrations are greater with type II designs than with type I designs. Also, nesting of telescopes to increase collecting area is impractical. Instead, collecting area may be increased by increasing the grazing angle, thereby increasing the projected area on the aperture plane, while maintaining a usefully long focal length and acceptable plate scale. The increase in graze angle, however, limits the useful spectral bandwidth of the telescope so that most practical type II telescopes are used for the extreme to far ultraviolet and longer wavelengths (>100 Å).

The type III design employs the outer surface of a paraboloid as the primary element and the inner surface of an ellipsoid as the secondary mirror. The paraboloid focus is coincident with one of the ellipsoid foci, and the image falls upon the other ellipsoid focus. The type III design has never been used for x-ray astronomy.

Wolter developed variants of the original designs by extending results obtained by Karl SCHWARZSCHILD in 1905 for normal incidence telescopes. The modified prescriptions are called Wolter–Schwarzschild (W–S) designs and differ slightly in their second-order figure (shape). These optics satisfy the Abbe sine condition strictly and so do not exhibit any comatic aberration. The improvement in off-axis performance of W–S designs over conventional designs is graze angle dependent. Thus W–S designs provide negligible improvement at the shallow graze angles (<1°) employed on many x-ray telescopes to achieve good reflectance at shorter wavelengths. W–S-type designs have been used on a number of extreme ultraviolet telescope applications which use much larger graze angles (>5°). The EXTREME ULTRAVIOLET EXPLORER (EUVE) contained a W–S type I EUV telescope and a W–S type II for the stellar spectrometer. ROSAT, besides carrying the large Wolter I x-ray telescope, also carried a W–S type I EUV telescope—the Wide Field Camera—which had a 5° field of view, ∼450 cm^2 aperture and image half-power diameter of ∼1.7 arcmin (on axis).

Contamination of the optical surface will degrade performance. Particulates both absorb and scatter the x-rays, degrading the point spread function and reducing the effective collecting area. Hydrocarbons absorb x-rays. Grazing incidence telescopes are extremely sensitive to both. This is a direct result of the shallow grazing angle, as can be seen in figure 5. A round particle of cross section πa^2 maps onto an entrance aperture area of $2\pi a^2$ because x-rays may strike the particle before or after reflecting off the mirror surface. The mirror surface area is $2\pi RL$ where R is the average radius of the nearly conical optic. The mirror entrance aperture has an area of $2\pi RL\sin\alpha$. Thus the fraction of mirror surface area F_{n} covered by the particle is

$$F_{\text{n}} = \frac{\pi a^2}{2\pi RL} \qquad (7)$$

but the fraction of the entrance aperture F_{A} 'covered' by the particle is

$$F_{\text{A}} = \frac{2\pi a^2}{2\pi RL\sin\alpha} = F_{\text{n}}\frac{2}{\sin\alpha} \qquad (8)$$

For a 1° graze angle F_{A} is ∼114 times larger than F_{n}. Similarly for a hydrocarbon layer t thick, the x-rays

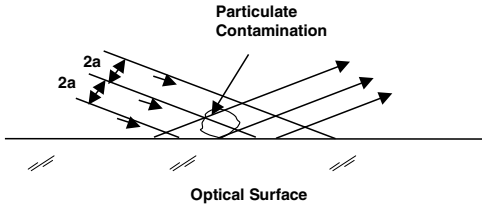

Figure 5. Illustration of the effects of particulate contamination. Incident x-rays from the upper left are absorbed or scattered by the particle either when directly impinging upon it or when impinging upon it after reflection from the mirror.

must traverse a distance $2t/\sin\alpha$. In addition, because of their construction with little space between telescope shells and very narrow entrance and exit annuli, it is extremely difficult to clean a dirty grazing incidence optic. Contamination control is a critical issue for grazing incidence optics.

Finally, an earlier realization than the Wolter designs was the Baez–Kirkpatrick telescope in which an array of parallel plates, parabolic in the plane of incidence, focus the incident x-rays to a line image. Placing a second set of plates oriented at a right-angle to the first set focuses the line image to a point image. This design has more aberrations than the Wolter designs, but may be approximated using optically flat plates bent in one axis so as to inexpensively build up large collecting area with moderate resolution.

Multilayer telescopes

Conventional optical telescope designs, when used as the substrate for multilayer coatings, are suitable for x-ray telescopes. The distinction between normal incidence x-ray and optical telescopes is that optical telescopes are diffraction limited and x-ray telescopes (to date) are not. To achieve diffraction-limited performance, the telescope wavefront error must be less than $\sim\lambda_x/13$, rms, where λ_x is the x-ray wavelength. For a two-mirror system being used at 171 Å, this equates to a surface error figure of ~5 Å, rms, or better than $\lambda/1300$ ($\lambda = 633$ nm), rms (neglecting other error contributors such as mirror figure degradation due to coating, support deformation, misalignments, etc). The ability to manufacture such optics is only starting to be feasible at the end of 1999. In addition, because of the short wavelength (relative to visible light) and current detector technology, extremely long focal lengths (>10 m) are required to make use of diffraction-limited performance.

Mechanical stresses in the multilayer coating can produce deformations of the optic, degrading imaging. Recent studies have shown that the stresses do not appear to vary as a function of the layer pair thickness, but do vary as a function of the equivalent d thickness and the materials. Thin-film technologists have found that coating stresses are also functions of a number of deposition parameters including substrate temperature and deposition process. Thin-film stresses may be estimated from Stoney's equation:

$$\sigma_f = \frac{E_s t_s^2}{6(1-\nu_s)t_f}\,\Delta C \tag{9}$$

where E_s, ν_s and t_s are, respectively, Young's modulus, the Poisson ratio and the thickness of the substrate, t_f is the thickness of the coating, ΔC is the change in radius of curvature of the substrate after the coating is applied and σ_f is the induced stress (a negative value of σ_f is compressive). Typical stresses range from −1200 to +200 MPa. These stresses can produce significant deformations on thin substrates, requiring either a modification of film or substrate design, or the use of post coating stress reduction techniques such as annealing (annealing, however, may cause diffusion across the interfaces, degrading reflectance).

Design, specification, and performance

Typical design constraints for an x-ray telescope will include focal length, spectral bandwidth, collecting area, resolution or fractional encircled energy, and size and weight. Not always independent of one another, these constraints determine whether a normal or grazing incidence telescope is desired, mirror figure requirements, coating design and element size.

Spectral bandwidth can determine whether an NI or a GI telescope is more appropriate. For extreme ultraviolet and very soft x-rays with wavelengths greater than ~100 Å, NI multilayer telescopes offer lower cost, better imaging and larger collecting area. Spectral regions above 0.1 keV are better served by GI optics which offer much greater reflection efficiency and better performance.

Diffraction by the annular entrance aperture can be significant at low energies. The intensity as a function of radial position x is expressed as:

$$I(x) = \frac{4}{[1-(r_i/r_o)^2]^2}\left[\frac{J_1(x_o)}{x_o} - \left(\frac{r_i}{r_o}\right)^2\frac{J_1(x_i)}{x_i}\right]^2$$

where

$$x_o = 2\pi r_o\frac{x}{\lambda f} \qquad \text{and} \qquad x_i = 2\pi r_i\frac{x}{\lambda f} \tag{10}$$

where r_o and r_i are the outer and inner radii of the annular aperture, respectively, f is the focal length, J_1 is the first-order Bessel function and λ is the incident wavelength. For NI telescopes diffraction does not limit imaging performance until one produces extraordinarily precisely figured optics, as discussed above in the section 'Multilayer telescopes'. Depending on telescope size, aperture diffraction can be more significant for GI optics. For example, the X-Ray Telescope (XRT) on the joint US–Japan Solar-B satellite has an aperture width of about 0.6 mm and an outer radius of ~170 mm. At a wavelength of 60 Å, the 68% point of the fractional encircled energy (the radial integral of the normalized point spread function)

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

is about 1.4 arcsec in diameter. For the large Chandra aperture diffraction is negligible.

Grazing angle, focal length and radius are related by the relation

$$\alpha = \frac{1}{4}\tan^{-1}\frac{r_0}{Z_0} \tag{11}$$

where α is the graze angle at the intersection of the paraboloid and hyperboloid surfaces, and r_0 is the radius of the virtual joint (Z_0 is not the focal length but it is fairly close). The choice of graze angle affects the short-wavelength limit of the telescope because of the precipitous loss of reflection efficiency near the critical angle. Therefore spectral bandwidth coupled with focal length can drive the maximum allowable optic size. From these few parameters one can derive the optical prescription of the paraboloid and hyperboloid using the method of Van Speybroeck and Chase (1972). If we constrain the graze angle of the hyperboloid at the virtual joint to be 3 times that of the paraboloid, then the prescription of the optics can be determined as

$$P = Z_o \tan(4\alpha)\tan\alpha \tag{12}$$

$$d = P \tag{13}$$

and

$$e = \cos(4\alpha)[1 + \tan(4\alpha)\tan(3\alpha)] \tag{14}$$

where the optical surfaces are represented as

$$r_p^2 = P^2 + 2PZ + 4e^2Pd/(e^2 - 1) \qquad \text{paraboloid} \tag{15}$$

and

$$r_h^2 = e^2(d + Z)^2 - Z^2 \qquad \text{hyperboloid} \tag{16}$$

and Z represents the coordinate along the optical axis and is zero at the system focus and e is the eccentricity. The effective focal length of the system, fL, is expressed as

$$fL = \frac{2e^2d}{e^2 - 1}. \tag{17}$$

(The ratio of fL/Z_o is a function of α and is approximately equal to $1 + 0.0025\alpha_{\text{deg}}^2$.)

Typically, performance of GI systems is expressed in terms of the encircled energy (usually as a fraction or as a per cent). This is the integral of the point spread function within a given angular diameter. One can think of the encircled energy as the fraction of incident flux that falls on a detector pixel or some other suitable area (e.g. a slit for some spectroscopy applications). It is a measure of how compact or spread out the light from a point source is imaged. The encircled energy may be normalized or scaled two different ways. In the first, normalization is with respect to the flux that leaves the last focusing optic (reflection losses are ignored). In the second approach the normalized encircled energy is scaled by the entrance aperture area and has units of area.

Image quality is affected by mirror surface imperfections (figure error and microroughness) which scatter the incident flux and broaden the point spread function. For conceptual purposes mirror errors may be loosely grouped into three categories. Low spatial error frequencies (long error periods) produce small-angle scatter which has only a small effect on the image 'core'. Mid-spatial-frequency errors produce intermediate-angle scattering and can have a significant effect on the image core, limiting resolution—the ability to discern two closely placed sources. High spatial error frequencies (typically microroughness) produce large-angle scatter (this might be on the order of 10–100 arcsec and greater) which degrades image 'contrast'—the ability to find a dim source in the presence of a bright source. The definition of what error frequencies correspond to the various bandwidths is dependent on the system requirements and grazing angle. On Chandra, errors that scatter x-rays by 0.5 arcsec would be considered mid-frequency. On XMM, mid-frequency errors might be considered as those that scatter by 5 arcsec.

A zeroth-order estimate of encircled energy can be made using the total integrated scatter, or TIS. This term represents the fraction of incident energy that is scattered by a surface (or equivalent surface) with a given rms surface figure error. The fractional encircled energy (or EE) is approximately $1 - \text{TIS}$. The EE is both incident wavelength and included angle dependent, so the choice of rms figure error must take this into account. This is done by using a bandlimited rms amplitude and making the assumption that this amplitude includes all surface error frequencies that will scatter the light outside the desired region of interest. The encircled energy is expressed (approximately) as

$$\text{EE} \approx \exp[-(2k\sigma\sin\alpha)^2] \tag{18}$$

where k is equal to $2\pi/\lambda$, σ is the bandwidth-limited effective rms surface error (in the plane of incidence) and α is the average graze angle. Using encircled energy goals we can estimate an acceptable value for σ, or, alternatively, σ can be used to estimate EE. (Of course, we want to leave some additional margin as we recognize that pointing stability–jitter, alignment, etc will all degrade performance.) To determine the bandwidth for which σ applies we use the grazing incidence equivalent of the grating equation (making use of the small-angle approximation)—

$$\lambda f = \theta_s \sin\alpha \tag{19}$$

where λ is the incident wavelength, f is the spatial frequency of the surface error and θ_s is the angle through which the radiation is scattered. All errors of higher spatial frequency will scatter through larger angles and fall outside the region of interest. In doing this analysis we are mostly concerned with errors in the axial direction. This is because the deviation of specular rays out of the plane of incidence by azimuthal errors is reduced by a factor of $\sin\alpha$. Similarly, the scattering distribution is elongated in the plane of incidence by a factor of $1/\sin\alpha$ (the grazing incidence foreshortens the spatial error periods in the plane of incidence, making the errors appear as a

higher-frequency and increasing the scattering angle (see equation (19))).

A more exact method of computing telescope requirements and estimating performance is obtained using the scalar scattering theory of Beckmann and Spizzichino. (Vector scattering theory may also be used for modeling performance. Some references by E Church are listed in the bibliography.) The output intensity distribution is given as

$$\frac{\mathrm{d}P}{\mathrm{d}\Omega_{\mathrm{total}}} = \mathrm{Strehl}\frac{\mathrm{d}P}{\mathrm{d}\Omega_{\mathrm{spec}}} + \frac{\mathrm{d}P}{\mathrm{d}\Omega_{\mathrm{spec}}} \otimes \frac{\mathrm{d}P}{\mathrm{d}\Omega_{\mathrm{scatt}}}. \qquad (20)$$

Strehl is the Strehl ratio and equals the right-hand side of equation (18). $\mathrm{d}P/\mathrm{d}\Omega_{\mathrm{spec}}$ is the intensity distribution in the absence of scattering–diffraction, such as results from large-scale geometric figure and alignment errors, $\mathrm{d}P/\mathrm{d}\Omega_{\mathrm{scatt}}$ is the scattered intensity distribution and $\otimes$ signifies a convolution operation. Using scattering theory to determine $\mathrm{d}P/\mathrm{d}\Omega_{\mathrm{scatt}}$ and integrating over $\mathrm{d}\Omega$ yields the encircled energy. After much algebra this can be reduced to a one-dimensional integral where the scattering is a function of the Fourier transform of the optic axial figure error power spectrum density (PSD). Thus, by measuring the axial surface errors (i.e. the axial one-dimensional profiles), computing the error PSD and measuring the geometric in- and out-of-plane contributors, we can estimate performance. Initially appearing complex, this formalism is very useful because optic (and replication mandrel) fabrication processes are essentially surface filters. Imaging performance is a function of surface error PSD, and optical fabrication technology provides a means to operate on the surface error PSD. This approach provides much more fabrication guidance than merely specifying a single bandlimited rms amplitude as an optic requirement. This approach also correctly takes into account the impact of the frequency content of the figure errors in estimating performance.

Fabrication

Grazing incidence telescopes are produced by one of several methods: direct polishing of the optics, replication of polished mandrels or forming of thin foils. Multilayer telescopes are manufactured using standard precision optical fabrication methods but require the application of the multilayer coatings.

Material considerations for x-ray optics are important. Since all x-ray observations are made in space, the optical elements must be strong enough to survive rocket launch acoustic and seismic loads. At the same time, optic weight must be minimized to reduce payload weight. Depending on the complexity of the spacecraft an active temperature control system may or may not be present, so mirror elements should have both a low coefficient of thermal expansion (CTE) and a uniform one. This minimizes optic distortion due to temperature variations and gradients in the spacecraft as it orbits the Earth.

Typical glasses used for x-ray telescopes are Zerodur™, a glass ceramic produced by Schott with an extremely low CTE, and ULE™ (which stands for ultralow expansion) produced by the Corning Glass Co, another very low-CTE glass. Fused quartz was used for the Einstein Observatory mirrors. Potential new materials include silicon carbide which has an extremely high strength to weight ratio offering the promise of very light weight non-replicated optics.

Optical fabrication of grazing incidence optics

Optic blanks arrive from the glass supplier as rough machined pieces, within 250–1000 μm of final dimensions (by contrast, final allowable figure error might be only a few hundred Ångströms, rms, or 10^4–10^5 times better). A carefully scripted material removal schedule utilizing ever-finer grinding grits and polishing compound is used to coarse figure the optics and remove residual machining stresses (subsurface damage, or microcracks) that can degrade figure stability or even lead to catastrophic failure under load. The inside (optical surface), outside and ends of the blank are polished for damage removal, to provide a surface that is easily cleaned and kept free of contamination, and to provide a controlled bonding surface for the optic mounting system.

The optical surface is figured in (grinding and) polishing using computer-controlled fabrication technology where a computer provides a set of commands to move the polishing head in a controlled fashion over the surface of the optic. Typically, the optic is supported with its axis nearly horizontal, the optic is made to rotate about its axis at a controlled rate, and the polishing tool is driven axially along the optical surface to describe a fixed path (e.g. a spiral), but with variable path velocity. Since material removal is inversely proportional to the path velocity, control of that velocity allows correction of the optical figure. The velocity commands result from deconvolving the polishing tool material removal profile from the optic surface error map. The fabrication process, along with the associated measurements, is iterative with typical error correction rates of 50–90% per iteration depending on the optics manufacturer. For Chandra, the correction rates were typically 85–95% depending on the error spatial frequency content.

Smoothing of the optic, critical for controlling scatter, is usually performed as a separate operation from figuring. ROSAT optics were smoothed to surface roughness levels of about 3 Å, rms, and the Chandra optics were smoothed to about 2–3 Å, rms.

The combination of computer-controlled fabrication and smoothing function as spatial frequency filter operations, making them readily linked to the PSD requirements that can be generated from the encircled energy requirement.

Because of the unusual optic geometry, most fabrication and metrology equipment is custom designed by the manufacturer. For larger optics such as on ROSAT and Chandra specialized handling equipment is also required.

Fabrication of grazing incidence optics by replication
When extremely good imaging (less than a few arcsec diameter) is not required, or when extremely large collecting area is required, replicated optics can be a superior alternative to individually fabricated glass optics. In this approach a set of replication mandrels that are the inverse of the desired final figure are fabricated first. Multiple replicas, each the inverse of a mandrel and therefore possessing the desired mirror figure, are then formed.

The advantages of replication are several. First, when multiple copies of the same mirror are required, replication is cheaper and less time consuming than individually fabricating each mirror. Second, many more shells can be nested within one another (without unduly growing the size of the outermost elements) because the replicas are typically much thinner than glass elements. This results in higher telescope 'throughput'. Third, because of their relative 'thinness' replicated optics may weigh substantially less than corresponding glass elements, reducing payload weight. (As an example, the largest X-ray Multi-mirror Mission (XMM) replicated nickel optics are less than 1/4 the weight per unit axial length of the corresponding size Zerodur™ Chandra counterparts.) These advantages mean that either the instrument can carry multiple copies of the telescope optics and detector (such as XMM) or multiple identical satellites can be placed in orbit (such as planned for Constellation-X). Replication is a way to achieve much larger collecting area and higher telescope throughput with lower weight per unit area at less cost than with non-replicated elements.

The disadvantage of replication (to date) is the level of figure quality which may be achieved, limiting imaging performance to ~14 arcsec, half power diameter (or 50% encircled energy). The mandrels themselves may be fabricated with the same accuracy as large glass elements. The difficulty arises in attempting to remove the lightweight replica from the mandrel, maintain its figure against internal stresses created while producing the replica and then support it for flight, without introducing low spatial frequency distortions in the figure.

The strengths of replicated optics and individually figured optics telescopes such as XMM and CXO are complementary. Replicated telescopes, with their large collecting area and good imaging capabilities, are generally more useful for imaging spectroscopy. For bright objects, however, telescope throughput is not a limiting factor and the full imaging capabilities of glass optics can be brought to bear. Replicated optics are more suitable for some observations of very faint objects or deep sky surveys where the photon noise limit obviates finer resolution, but the limiting angular resolution may also result in an inability to resolve discrete sources. Alternatively, glass optic telescopes may be limited in the number of deep surveys possible owing to the extended observing time needed to collect enough photons necessary to make full use of their imaging.

Several methods of replication are briefly described below.

Nickel replicas An aluminum mandrel is coated with ~200 μm of electro-less nickel (Kanigen). The electro-less nickel surface is loose abrasive ground and computer-controlled polished or diamond turned to the nominal figure (after diamond turning additional figuring may be required). The surface is smoothed (polished) to about 5 Å, rms, roughness, to complete the mandrel. The replica is produced by first depositing 100–200 nm of gold on the electro-less nickel surface and then electroplating the gold with nickel to the desired thickness (~1 mm). The replica is separated from the mandrel by cooling the mandrel (the coefficient of thermal expansion for aluminum is about twice that of nickel). The gold coating separates with the nickel replica because its adhesion to the electroplated nickel is much greater than to the Kanigen. Multiple replicas may be made from a single mandrel before the mandrel needs to be refurbished. Replicas of this type have been used for the BEPPOSAX, JET-X and XMM. Replica sizes range from 300 mm long, 68 mm diameter on BeppoSAX to 600 mm long, 700 mm diameter on XMM. The half-energy width of the point spread function at 1.5 keV is 13 arcsec for XMM.

As previously mentioned, internal stresses in the electroplated nickel will deform the replica when it is removed from the mandrel. Potential solutions to the lack of structural rigidity of these replicas include the use of stiffening structures fixed to the replica during the nickel plating process and the use of ceramics or silicon carbide (SiC) in place of the nickel replica substrate. In the latter approach the SiC substrate is formed to near final shape by chemical vapor deposition (CVD) to a second mandrel slightly larger (10^2 μm) than the first. The first mandrel is coated with 100 nm of gold, and then the SiC substrate is positioned around it. The gap is filled with epoxy, and, after curing, the gold-coated epoxy/SiC replica is separated from the Kanigen-coated aluminum mandrel by cooling. The CVD SiC has little residual internal stress and has a Young's modulus approximately 3 times larger than that of nickel. The SiC replica can be made substantially thinner than the nickel replica. A similar process using a beryllium substrate instead of SiC has been used on the Exosat program. An alternative approach in which aluminum oxide is plasma sprayed directly on the gold-coated Kanigen/aluminum mandrel is also under investigation at the time this article is being written.

Epoxy replicas In epoxy replication an aluminum foil serves as the replica substrate. A glass (Pyrex™ or Zerodur™) mandrel is coated with ~100 nm of gold. A thin (~100 μm) aluminum foil is pre-formed to the approximate shape of the coated mandrel but slightly oversized. Both the gold-coated mandrel and the (inner) surface of the foil are sprayed with epoxy and the two are then mated. The epoxy film, several tens of microns thick, is cured in an oven before the foil is removed. The foil maintains the smoothness of the polished glass mandrel. Epoxy replicas have not at this time achieved the imaging capabilities of nickel replicas, but the replicas

Table 1. An abbreviated list of some of the more notable x-ray telescopes.

Mission	Type	Effective area (cm^2)	Resolution (HPD, arcsec)	Energy bandwidth[a] (keV)	Comments
Skylab (1975)	GI	42 (collecting area)	~2 arcsec resolution	0.2–2	First x-ray telescope; solar observations
Einstein Observatory (1978–81)	GI	~200 at 1 keV	~15	0.2–4.5	First telescope observatory; discovered 7000+ sources
RXRS[b] (1987)	NI	~50 (collecting area)	~2 arcsec resolution	17.3, 25.6 nm	First NI solar telescope(s); 6.3 cm diameter primary mirror
ROSAT (1990–9)	GI	400 at 1 keV	~5	0.1–2.4	4 Au coated Zerodur shells; discovered 150 000+ sources
ASCA (1993)	GI	1300 at 1 keV, 600 at 7 keV	174	0.5–10	Conical foil Al mirrors, Au coat over lacquer, 4 separate telescopes
BeppoSAX (1996)	GI	330 at 1 keV	60	0.1–10	Nickel-replicated conical optics, 30 nested shells
TRACE (1998)	NI	~20	1	17, 20, 28 nm	30 cm diameter primary, 2 m focal length solar telescope
Chandra (1999)	GI	800 at 1 keV	0.5	0.1–10	Highest resolution, 4 shells, largest mirror 1.2 m diameter transmission gratings
XMM (1999)	GI	4650 at 1 keV, 1800 at 8 keV	14	0.1–12	Nickel replicas, 3 telescopes, 58 shells each, reflection gratings
Constellation-X (200?)	GI	15 000 at 1 keV 1500 at >6 keV	15 (<10 keV) 60 (>25 keV)	0.25–10, 6–40	Replicated optics (type to be determined), ~80+ shells, largest 1.2 m diameter grating

[a] For NI telescopes the tabulated values represent the approximate centers of the reflection bandpass(es).
[b] Stanford University/NASA Marshall Space Flight Center Rocket X-Ray Spectroheliograph.

are substantially lighter owing to their much thinner wall and less dense substrate material. To date limiting performance is ~1 arcmin.

Segmented foil replicas Segmented foil mirrors have been used on the Broad Band X-Ray Telescope (BBXRT), ASCA and the Sodart telescope on board SPECTRUM-X-GAMMA. Here the mirrors do not form the complete surface of revolution, but instead form (typically) only a single quadrant. Aluminum foils less than a millimeter thick and optically smooth are rolled into a 90° section of the desired conical shape (note that the mirrors, being true cones, are only approximations to Wolter I telescopes). Plastic deformation (rather than elastic bending) is employed to produce a final shape that more closely approaches the nominal and does not introduce stresses into the support structure. After rolling, the foils are dip-coated with an acrylic lacquer to improve (reduce) scattering due to surface roughness. Care is taken to avoid introducing variations in lacquer thickness that would change the optical shape of the mirror, degrading imaging. Mirrors of this type are very inexpensive to produce but have not achieved better than a few arcminutes resolution. In part this limitation is a result of the approximation to a Wolter I system, but, more importantly, it appears that the lacquer is ineffective at smoothing errors with spatial periods greater than a few microns. These errors significantly affect the ability to image at better than the 1 arcmin level.

Fabrication of normal incidence multi-layer telescopes Normal incidence x-ray multilayer telescopes are essentially manufactured using the same processes as conventional precision optics with two major exceptions: optic smoothness (or microroughness), which affects both scatter and multilayer reflectivity, and the deposition of the x-ray multilayer coating.

As discussed above in the section 'Reflection from multilayer coatings' reflectance is a function of high spatial frequency roughness ($f > 10^3$ mm^{-1}). Super-smoothing of the surface roughness in this very high spatial frequency regime to levels of 2–4 Å, rms, is necessary for good reflectance.

Along with substrate roughness, the multilayer coating is the most critical element of the optics. To achieve the desired reflectance over the correct spectral bandwidth requires uniformity of coating thickness both across the face of the optic as well as from layer to layer. Coating

density must also be uniform throughout the multilayer. In addition, interlayer diffusion must be minimized as must thin-film stresses.

Telescope systems

Other parts of a telescope system are the detector, optical bench and mirror mount or support structure. CHARGE COUPLED DEVICES (CCDs) have supplanted position-sensitive proportional counters. CCDs may be either front or back illuminated. Front-illuminated CCDs have the x-rays impinge upon the semiconductor gate side. Back-illuminated CCDs have additional wafer processing to thin the backside of the chip (the side away from the gates) and are then set so that the x-rays impinge upon the backside. Front-illuminated CCDs provide better energy resolution and slightly higher quantum efficiency at high energy than back-illuminated CCDS. Back-illuminated CCDs provide substantially higher low-energy x-ray quantum efficiency. A wide range of pixel sizes are available: the Chandra CCDs have 24 μm pixels; the Solar X-ray Imager (SXI) on GOES N and O will have $\sim$15 μm sized pixels. The long focal length ($\sim$10 m) of Chandra coupled with 24 μm pixels yields $\sim$0.5 arcsec angular resolution. CCDs provide excellent energy resolution, about 120 eV for the Chandra detectors. Several CCDs may be arrayed to cover the full field of view of the telescope, and the detectors may also be arrayed so as to be aligned to the curved focal surface, thereby eliminating focus error that occurs with a flat detector and a curved focal surface (see equation (6)). Higher imaging resolution is achieved with less energy resolution using detectors such as the Einstein, ROSAT and Chandra High Resolution Imager. This is a pair of stacked multichannel plates with an electronic readout. Future developments include the use of microcalorimeters, which will be used for the first time on Astro-E. This device has an energy resolution of $\sim$12 eV at 6 keV but has a relatively large pixel size and so limits spatial resolution. Spectroscopy with x-ray telescopes is also accomplished by the use of transmission gratings that may be moved in and out of the focused beam, such as on Chandra, or reflection gratings fixed in the beam as on XMM.

X-ray telescope missions

Some significant x-ray telescopes and performance details are listed in table 1.

Future trends

In grazing incidence telescopes future trends will continue the development of increased collecting area, improving resolution and increasing reflectance. The use of ceramics and SiC, including the use of monolithic support structures, will improve the limiting performance of what used to be nickel mandrels, while also allowing denser nesting of mirror shells. Researchers have been experimenting with the application of broadband multilayer coatings to grazing incidence optics, increasing reflectance at higher energies. With respect to normal incidence telescopes future development will probably focus on achieving diffraction limited performance with increased focal lengths to more fully utilize the improved optics.

Bibliography

There are a multitude of excellent articles in the literature discussing the technology of x-ray telescopes. For design issues of GI telescopes one is referred to

X-rays

Energetic electromagnetic radiation with wavelengths in the range 10 nm (10^{-8} m) down to 0.01 nm (10^{-11} m). Although the boundaries are somewhat arbitrary, wavelengths shorter than 0.01 nm are called gamma-rays and those longer than 10 nm extreme ultraviolet (EUV). Cosmic x-rays are usually described in terms of photon energies, a wavelength of 10 nm corresponding to an energy of 80 electron volts (eV) and a wavelength of 0.01 nm to 8×10^5 eV (80 keV).

X-rays from cosmic sources are absorbed high in the Earth's atmosphere. Even the most energetic (shortest-wavelength) x-ray photons fail to penetrate much closer to the ground than an altitude of about 40 km.

X-rays were discovered in 1895 by the German physicist Wilhelm Konrad Röntgen (1846–1923).

Yarkovsky Effect

The Yarkovsky effect changes the rotation and the orbit of a body orbiting in the Solar System by the asymmetrical re-radiation of thermal energy from the Sun. The effect constitutes a non-gravitational force which causes the orbits of smaller, kilometer-sized asteroids to change over time.

Year

The period of the Earth's revolution around the Sun, or of the apparent motion of the Sun on the ecliptic. It may be defined in a number of ways, each of which leads to a slightly different value:

Sidereal year. The time interval during which the Sun apparently completes one revolution of the celestial sphere relative to the stars (which, for this purpose, are regarded as being fixed in space). This is equal to the revolution period of the Earth around the Sun as measured relative to the stars, and is equivalent to 365.2564 mean solar days.

Tropical year. The time interval between two successive passages of the Sun through the vernal equinox. Its length is 365.2422 mean solar days, about 20 minutes shorter than the sidereal year. The difference arises because of the effects of precession. As this definition of the year is related to the recurrence of the seasons, the term 'year', if unqualified, is generally taken to mean 'tropical year'.

Anomalistic year. The interval between two successive passages of the Earth through the perihelion of its orbit which, because of a slow change in the position of perihelion, is not quite the same as the sidereal year. Its length is 365.2596 mean solar days.

Gregorian calendar year. This is the value of the year adopted for calendar purposes, and is equal to 365.2425 mean solar days. For practical purposes it can be taken as equal to the tropical year (the difference amounts to 0.0003 mean solar days).

Yerkes Observatory

Yerkes Observatory lies 334 m above sea level in Williams Bay, Wisconsin. It is a research branch of the Department of Astronomy and Astrophysics of the University of Chicago.

The observatory was completed in 1897. It was financed by Charles Tyson Yerkes, a Chicago transportation tycoon, but the inspiration behind its construction was George Ellery Hale. The showpiece of the observatory was the 1 m refractor, the world's largest telescope in 1897, and still the largest refracting telescope ever built.

Until the mid-1960s, Yerkes Observatory housed all of the university department's activities (including managing the operations for MCDONALD OBSERVATORY in Texas from 1932–62). Today, the 77 acre site provides laboratory space and access to telescopes for research and instruction. A substantial fraction of the university's library holdings in astronomy are housed at Yerkes.

The principal telescopes are the 1 m refractor, a 1 m Ritchey–Chrétien reflector which is used for adaptive optics studies, a 0.6 m reflector and an 18 cm Schmidt camera for wide-field photography.

Recent research at Yerkes includes measuring the velocities and distances of the furthest star clusters within the Milky Way to better determine the mass of our Galaxy; spectroscopic measurements of lithium abundances; spectra of the dust disk around Beta Pictoris; and studies of the properties of distant galaxies. Yerkes astronomers are currently developing a camera for the airborne Stratospheric Observatory for Infrared Astronomy (SOFIA).

Yohkoh

The Yohkoh satellite was launched by Japan's INSTITUTE OF SPACE AND ASTRONAUTICAL SCIENCE (ISAS) on 30 August 1991 for observations of solar FLARES and the solar CORONA in x-ray and gamma-ray wavelengths. Excellent observations have been made over the last nine years (see figures 1 and 2). The satellite has experienced the entire transition from the maximum to the minimum of the last SOLAR CYCLE and is proceeding to observations of the rising phase of solar cycle for the first time.

Yohkoh carries two X-RAY TELESCOPES: the hard x-ray telescope has imaging capability above 40 keV because of its utilization of modulation collimators. These hard x-ray images allow us to obtain new information on where and how energetic electrons are accelerated in solar flares. The soft x-ray telescope is a grazing-incidence x-ray (5–50 Å) telescope to observe the solar corona and solar flares with high spatial (3 arcsec) resolution. The soft x-ray telescope is sensitive to plasmas with temperatures from 2 MK through 20 MK. Two other instruments onboard are the Bragg crystal spectrometer to observe the iron, calcium and sulfur lines from flare plasmas and the wide-band spectrometers to observe flare spectra from 5 keV to 10 MeV.

The discoveries made so far by Yohkoh cover a wide area of solar physics. In the following, we give representative examples.

(1) *Mechanism of solar flares*. The Yohkoh data, for the first time, showed unambiguously that magnetic reconnection is responsible for significant energy release in solar flares; intense heating occurs owing to magnetic reconnection possibly with standing slow magnetohydrodynamic shocks.

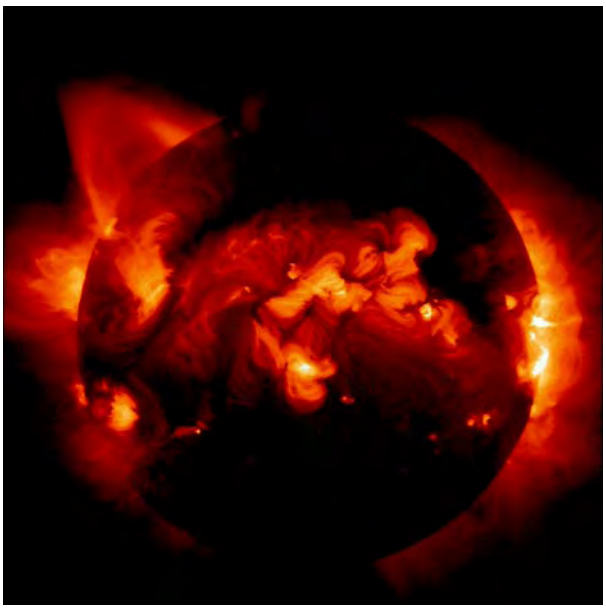

Figure 1. X-ray image of the Sun taken with Yohkoh.

(2) *Microflares and coronal heating*. Yohkoh x-ray movies showed numerous small transient brightenings far smaller than flares in energy (microflares) as well as structural changes of coronal magnetic fields. Magnetic reconnection is again responsible for these brightenings. Although the heating mechanism of the persistent corona remains unknown, these observations imply that an ensemble of nanoflares, which are too faint to be resolved, maintains the persistent solar corona.

(3) *X-ray jets*. Yohkoh discovered x-ray jets with speed reaching several hundreds km s^{-1}. X-ray jets may be driven by the slingshot effect of the reconnected field lines or maybe due to chromospheric evaporation caused by heat flow from the reconnection site.

(4) *Electron acceleration in solar flares*. The Yohkoh hard x-ray telescope showed that hard x-ray flares essentially have double-source structures, which are located at the footpoints of the soft x-ray loop. This clearly indicates that a rich population of non-thermal electrons (up to 10 MeV or higher) are created in flare loops in association with magnetic reconnection and emit hard x-rays with bremsstrahlung. A surprising discovery from the hard x-ray observations is the detection of an impulsive hard x-ray source located above the soft x-ray loop. The loop-top source is due to bremsstrahlung of high-energy electrons with energy up to at least 50 keV. The energization probably occurs at the fast magnetohydrodynamic shock formed by the supersonic outflow from the reconnection site.

MAGNETIC RECONNECTION with associated slow magnetohydrodynamic shocks appears to be a powerful engine to convert magnetic energy to plasma kinetic and thermal energies. The hard x-ray observations also show that the resultant supersonic outflow creates fast shock, which converts the flow energy to further heating and/or non-thermal acceleration of electrons and protons as a result of Fermi acceleration. In spite of the large magnetic Reynolds number of the solar corona,Yohkoh has delivered unambiguous evidence of magnetic reconnection in flares and in the corona.

Yohkoh is therefore revolutionizing our understanding of the solar corona and the behavior of magnetized plasmas in general. Yohkoh shows for the first time how the Sun dynamically relaxes its magnetic energy, buoyant as a result of the subsurface dynamo mechanism, by the process of magnetic reconnection. The formation of the solar corona with frequent sporadic (10–100 Alfvén transit times) energy releases including solar flares, solar wind and coronal mass ejections is a consequence and manifestation of the energy release process. This suggests that magnetic energy conversion through magnetic reconnection is likely to be a common occurrence in the cosmos.

Young Stellar Objects

Young stellar objects (YSOs) are stars in the earliest stages of development. There are two principal kinds of YSOs: protostars and pre-main sequence stars. YSOs are intimately associated with fundamental by-products of the star formation process such as bipolar outflows, circumstellar jets, masers, Herbig–Haro objects, and circumstellar (protoplanetary) disks. YSOs are always found within or near interstellar clouds of gas and dust. Most YSOs populate giant molecular clouds and a significant number are members of fully or partially embedded stellar or protostellar clusters.

Background

Stars are the fundamental objects of the astronomical universe. They are self-gravitating balls of (mostly) hydrogen gas which convert the primary product of the big bang (hydrogen) into heavier elements. For most of its life a star maintains a state of stable equilibrium in which the inward force of gravity is balanced by the outward force of pressure. This internal pressure is generated by the energy released in the nuclear reactions which burn hydrogen at the star's center. These nuclear reactions are also the source of the star's luminosity. During the time the star burns hydrogen in its core it maintains a fixed radius and luminosity and consequently a constant surface temperature. The exact value of the equilibrium radius, luminosity and surface temperature of a star depends almost exclusively on one parameter, the star's mass (see STELLAR MASSES). The more massive the star, the greater its luminosity, size and surface temperature. Together, hydrogen burning stars of varying mass form a well defined locus of points in the observable luminosity–effective temperature plane (the HERTZSPRUNG–RUSSELL DIAGRAM). This locus of points is called the main sequence and the hydrogen burning phase of a star's life is known as the main sequence phase. Main sequence stars range in mass from about 0.08–100 $M_\odot$ (solar masses). Stars with smaller masses have insufficient weight to raise their central temperatures enough to enable hydrogen fusion. (Such objects are referred to as brown dwarfs.) Stars with larger masses are presumably too luminous to hold on to their outer atmospheres.

The formation and early evolution of stars

STAR FORMATION and early STELLAR EVOLUTION occur prior to the main sequence or hydrogen burning phase of stellar life. Most stars in the Galaxy originate in giant molecular clouds (GMCs). With temperatures seldom in excess of 10 K and maximum dimensions of 50–100 pc, GMCs are the coldest objects in the universe and the largest objects in the Galaxy. With masses in excess of $10^5\ M_\odot$ they also rival globular clusters as the most massive objects in the Galaxy. GMCs are composed primarily of molecular hydrogen and are characterized by mean densities of $\sim$100 cm^{-3}. About 10% of the mass of a typical GMC is in the form of dense cores with $n(H_2) \sim 10^4$ cm^{-3}. It is within such dense regions that stars are formed.

Although there is no complete theory of stellar origins, basic astrophysical considerations result in the following general picture of star formation and early stellar evolution. Stars form through the gravitational collapse of dense molecular cloud cores. Before being incorporated into a star, the interstellar material must increase its density by 20 orders of magnitude and collapse to a size nearly 7 orders of magnitude smaller than the dimensions of the original dense cloud core. Because the dust in the cloud is optically thin, internal energy gained by its collapse is effectively radiated away. Thus the cloud material remains isothermal and dynamically collapses. The collapse also proceeds in a non-homologous manner, with the inner regions becoming denser and collapsing faster than the outer regions which are left behind. Eventually, the innermost infalling material becomes dense enough to be optically thick to its own radiation resulting in the development of a central quasistatic stellar core surrounded by an infalling envelope. Thus is a protostar born.

After the formation of its embryonic core, the protostar enters the accretion phase of protostellar evolution. During this time the central stellar core gradually gains mass via the accretion of material from its infalling envelope. Before being finally incorporated onto the growing stellar core, accreting material must dissipate the gravitational potential energy lost in infall, giving rise to an accretion luminosity:

$$L_{\text{accretion}} = \frac{GM_*\dot{M}}{R_*}$$

where M_*, and R_* are the mass and radius of the protostellar core and $\dot{M}$, the mass accretion rate. This accretion luminosity can be a significant component of a protostar's luminosity. The mass accretion rate is generally expressed as:

$$\dot{M} = m_0\frac{a^3}{G}$$

where a is the effective sound speed and m_0 is a constant which is sensitive to the initial conditions in the collapsing core. Different theories of star formation predict somewhat different values of m_0. In some models m_0 varies with time and is quite large ($\sim$10) in the early stages of collapse, falling to near unity in the later stages. However, for most protostars, this constant must be near unity to be consistent with the observed luminosities of protostellar objects.

Initially the mass of the embryonic stellar core is very small, approximately $10^{-2}\ M_\odot$ and the central temperature of the core is not sufficient to ignite nuclear reactions. As the embryonic core begins to grow its luminosity is dominated by accretion. The mass of the protostellar core increases as $M_*(t) = \dot{M}t$. Once a protostellar core reaches a mass of roughly 0.2–0.3 $M_\odot$, its central temperature reaches

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

10^6 K and deuterium-burning nuclear reactions are ignited providing the protostar with another source of luminosity. ACCRETION of new material and a fully convective core enable the protostar to continue burning deuterium as it grows. If placed on the HR diagram the protostellar core would follow a trajectory parallel to and somewhat above the deuterium-burning main sequence which itself lies significantly above and roughly parallel to the (hydrogen-burning) main sequence. A protostellar core can continue to gain mass by accretion until its central temperature reaches 10^7 K and hydrogen fusion is ignited, at which point the embryonic core reaches the main sequence. This occurs when the cores attain masses around 7–8 solar masses. Presumably, the protostar can still continue to grow and increase its mass. However, for reasons not yet fully understood, most protostars cease growing long before this point. In any event, stars which end up with masses in excess of 7–8 solar masses have a very different post-protostellar evolution than stars which end up less massive.

The physical reason for this becomes apparent if one compares the timescale for pre-main sequence evolution with that of protostellar collapse. The timescale for the gravitational collapse of a cloud core, the free-fall time, is determined largely by ρ, the density of the cloud:

$$\tau_{\rm ff} = \sqrt{\frac{3\pi}{32G\rho}}.$$

For the typical mean density ($n \approx 10^4$ cm^{-3}) of a cloud core (of either low or high mass) the free–fall time is about 4×10^5 yr. The timescale for pre-hydrogen-burning evolution is the Kelvin–Helmholtz time:

$$\tau_{\rm KH} \approx \frac{GM_*^2}{R_* L_*}$$

which is very rapid for a high mass star (i.e. $\approx 10^4$ yr for $M_* = 50\ M_\odot$) and relatively slow for a low mass star (i.e. $\approx 3 \times 10^7$ yr for $M_* = 1\ M_\odot$). More importantly for high mass stars $\tau_{\rm KH} < \tau_{\rm ff}$ and these stars begin burning hydrogen and reach the main sequence before the termination of the infall or collapse phase of protostellar evolution. On the other hand, for low mass stars $\tau_{\rm KH} > \tau_{\rm ff}$ and low mass stars have an *observable* pre-main sequence stage of stellar evolution.

The initial conditions for pre-main sequence evolution are those which describe the mass, radius and luminosity of an embryonic protostellar core at the the point in time that infall and accretion cease. For this reason the locus of points on the HR diagram which traces the initial starting points of PMS evolution for all stars is called the birthline. The position of a given star on the birthline is a function of the mass it has acquired by the end of its protostellar accretion phase. Presumably, the protostellar evolution of a given star is identical to that of all other stars until the time that the star stops accreting and reaches the birthline. Prior to its appearance near the birthline, a young stellar object is surrounded by an infalling protostellar envelope which renders it invisible. Once the envelope is either mostly accreted onto the protostellar core or removed by some agent, the protostar becomes a visible PRE-MAIN SEQUENCE STAR. Its initial luminosity and surface temperature place it near the birthline which, for low mass stars, is itself basically coincident with the deuterium-burning main sequence on the HR diagram. Because the abundance of deuterium in the young star is relatively low, it is burned up very rapidly. Without accretion to replenish the burned deuterium, nuclear reactions cease and the star slowly contracts to the main sequence. The timescale for this quasistatic contraction to the main sequence is the Kelvin–Helmholtz time.

Observational characteristics of the low mass young stellar objects

The evolutionary status of a normal star is usually determined by its placement on the HR diagram. This in turn requires measurements of two quantities: stellar luminosity and effective temperature. A star can be meaningfully placed on the HR diagram provided it emits a black-body-like spectrum that can be characterized by a single effective temperature. For YSOs this is not always possible. This is because throughout their formation and early evolution stars are intimately associated to varying degrees with natal gas and dust. This circumstellar gas and dust can absorb and reprocess substantial amounts of the radiation emitted by a young stellar object, significantly altering its spectral appearance. The circumstellar gas and dust associated with a young stellar object has a spatial extent considerably greater than that of its stellar photosphere. Consequently, emitting circumstellar dust, which is in radiative equilibrium with the stellar radiation field of the buried star, will exhibit a wide range of (effective) temperature and the emission that emerges will have a spectral distribution much wider than that of a single temperature black body. In addition, at the optical wavelengths the youngest objects are rendered completely invisible by the obscuration of opaque circumstellar dust and a significant fraction, if not all, of their luminous energy is radiated in the infrared portion of the spectrum.

To determine the evolutionary status of a young stellar object requires knowledge of its overall broadband energy distribution, particularly at infrared wavelengths. The shape of the broadband energy distribution of a YSO will depend on both the nature and distribution of the surrounding material. Consequently, the shape of the spectrum will be a function of the state of evolution of a YSO. The earliest (protostellar) stages, during which an embryonic star is surrounded by large amounts of infalling material, have a very different infrared signature than the more advanced (pre-main sequence and main sequence) stages, where most of the original star-forming material has already been incorporated into the young star itself. This is clearly apparent for low mass (0.1–2.0 $M_\odot$) YSOs where the majority of known sources can be meaningfully classified by the shapes of their observed

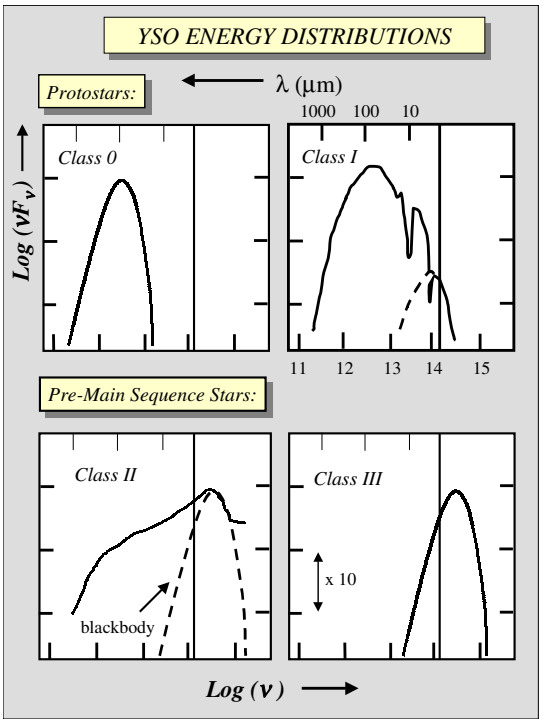

Figure 1. The classification scheme for the spectral energy distributions (SEDs) of young stellar objects. A vertical fiducial line is located at the infrared wavelength of 2.2 μm for reference. (Figure courtesy of C J Lada.)

spectral energy distributions (SEDs) into one of four broad classes designated 0, I, II and III (see figure 1).

Embedded sources: protostars

Class 0 and I sources are characterized by SEDs that peak in the submillimeter and far-infrared portions of the spectrum indicating that the SEDs are dominated by emission from cold dust (see CLASSIFICATION OF STELLAR SPECTRA). These objects are the most deeply embedded YSOs.

Class I SEDs are broader than a single black-body function. Longward of two microns these SEDs usually rise with increasing wavelength producing a huge 'excess' of infrared emission compared to that expected from a normal stellar photosphere. They typically exhibit the silicate absorption feature at 10 μm wavelength. Class I sources derive their large infrared excesses from the presence of large amounts of circumstellar dust. These sources are usually deeply embedded in dense molecular cloud cores and rarely exhibit detectable emission in the optical portion of the spectrum. However, they are detected at near-infrared (i.e. 2.2 μm) wavelengths and frequently associated with small (infrared) reflection nebulae. Indeed, a significant fraction, in some cases all, of the near-infrared emission from a class I source is scattered light. Roughly half of the class I sources exhibit atomic emission lines in the infrared. Otherwise, the infrared spectra of these objects are found to be featureless and heavily veiled. Class I sources are almost always associated with very energetic, relatively massive, collimated outflows of cold molecular gas known as bipolar outflows. The luminosities of class I sources in regions of low mass star formation typically range between 0.1–100 $L_\odot$. Class I sources are relatively rare among YSOs in molecular clouds and statistical arguments suggest ages of these sources of order 1–5 $\times$ 10^5 yr.

Class 0 sources are considerably more extinguished and embedded than class I sources. Their energy distributions peak at submillimeter wavelengths and most are not detected at wavelengths shortward of 20 μm. Unlike class I sources, their energy distributions have widths similar to single-temperature black-body functions however, they are characterized by extremely low temperatures, 20–30 K! All are associated with bipolar molecular outflows which are typically more energetic and much better collimated than those associated with class I objects. On the other hand, as a whole class 0 sources are not significantly more luminous than class I sources. In addition, some observations suggest that class 0 sources emit significantly more submillimeter radiation on small spatial scales than do class I objects. In particular, the circumstellar mass traced by submillimeter measurements within 1000 AU of a class I source is usually found to amount to a fraction of a stellar mass, while for a class 0 source this mass can be comparable to that of the central star. Class 0 sources are relatively rare making up roughly 10% of embedded sources. This suggests that their lifetimes are only of the order of $\sim 10^4$ yr, which is consistent with estimates of the dynamical ages of their associated outflows.

A subset of the class I sources, known as flat-spectrum sources, merit additional comment. Flat-spectrum sources are embedded YSOs that have SEDs intermediate between class I and II sources. Unlike the standard class I source, these objects are often visible stars which display extreme T Tauri characteristics. That is, they are optical emission-line variable stars, whose optical spectra display little in the way of photospheric absorption features and are heavily veiled (most likely by excess continuum radiation from accretion shocks at the stellar surface). Indeed, the most well known member of this group is T Tauri itself. Like class I sources, these objects are also veiled at infrared wavelengths, but not as strongly. Roughly half the flat-spectrum sources display atomic and molecular absorption lines at 2.2 μm. This is significant because these are the only embedded objects for which the inner stellar component can be spectrally classified and placed on the HR diagram. These objects are found to be characterized by late-type (M) photospheres whose luminosities place them near or above the birthline. Flat-spectrum sources appear to be objects in transition between the class I and II phases and can be considered 'optical protostars'.

The embedded sources are generally considered to be protostars. Operationally, we define protostars as YSOs in the process of accumulating into a stellar-like

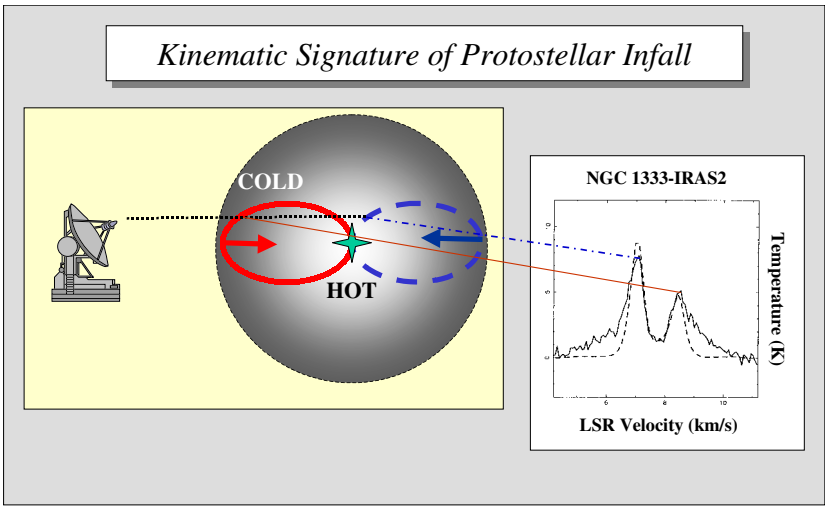

Figure 2. The expected kinematic signature of infall from gas surrounding a protostellar source. Oval curves represent lines of constant infall velocity. The thick dashed line represents blue-shifted gas, the thick solid line red-shifted gas. Along a single line-of-sight the radio telescope beam intercepts the $\tau = 1$ surface in the outer, colder regions of the cloud at redshifted velocities and the inner, hotter regions of the cloud at blueshifted velocities producing an asymmetric emission- line profile. The observed spectrum of carbon monoxide emission from the protostellar source NGC 1333 IRAS2 in Perseus is also shown. (CO spectrum adapted from Ward-Thompson *et al* 1996 *Mon. Not. R. Astron. Soc.* **314** 625.)

configuration the bulk of the material they ultimately will contain as main sequence stars. Evidence for a protostellar nature of the embedded sources is derived from the following considerations.

First, theoretical models of collapsing, rotating cloud cores predict the density and temperature structure of protostellar objects and these models produce SEDs which closely match those of known class I sources.

Second, the only viable source for the enormous energies of the bipolar outflows generated by class 0 and I sources is gravity. Specifically, it is the release of gravitational potential energy by material falling deep into the potential well of a protostellar system. That is, material falling all the way down to the surface of the embryonic stellar core. Exactly how this energy from infall and accretion is tapped to drive a protostellar wind is unclear. However, observational relations between accretion and outflow diagnostics suggest that the mass-loss rate characterizing the outflows is related to the mass accretion rate as $\dot{M}_{\rm wind} = f\dot{M}_{\rm accretion}$, with $0.01 \leq f \leq 0.1$.

Third, the observed veiling of class I spectra in the infrared requires the existence of dust very close (i.e. $\ll$1 AU) to the protostellar surface. Theoretical models predict that dynamically infalling protostellar envelopes contain enough such material close to the protostellar surface to account for the degree of observed veiling.

Fourth (and most significant), kinematic evidence for collapse has been observed toward a number of mostly class 0 sources. Under favorable conditions sub-millimeter and millimeter-wave spectral lines from collapsing clouds will display a kinematic signature of infall motion (see figure 2). This signature takes the form of an infall asymmetry in the line profile in which the redshifted portion of an optically thick emission line is depressed relative to the corresponding blueshifted portion. Surveys of embedded sources have revealed the infall symmetry towards a substantial number ($\sim\frac{1}{3}$) of class 0 sources. Such kinematic signatures provide the most direct evidence for infall and for a protostellar nature for these heavily embedded sources.

Revealed sources: pre-main sequence stars

Class II SEDs peak at visible or near-infrared wavelengths. Like class I sources the class II SEDs are broader than a single black-body function. However, longward of two microns class II SEDs fall with increasing wavelength usually in a power-law-like fashion. This results in an infrared excess which, though significant, is much smaller than that exhibited by class I sources. The infrared excess indicates the presence of circumstellar material associated with the star.

Theoretical calculations predicted more than two decades ago that T TAURI STARS would display such energy distributions if they were surrounded by luminous accretion disks. Consider an optically thick and spatially thin disk that surrounds a young star and radiates everywhere like a black body. Imagine the disk to be composed of concentric annuli with radial dimension ΔR and area $2\pi R\Delta R$ (see figure 3). Each annulus radiates as a blackbody of temperature $T(R)$. The emergent spectrum of the disk will then be the superposition of a series of black-body curves of varying $T(R)$. Now if $T(R) \sim R^{-n}$, the Wien law tells us that the frequency of maximum emission scales as $\nu \sim T(R) \sim R^{-n}$. The luminosity

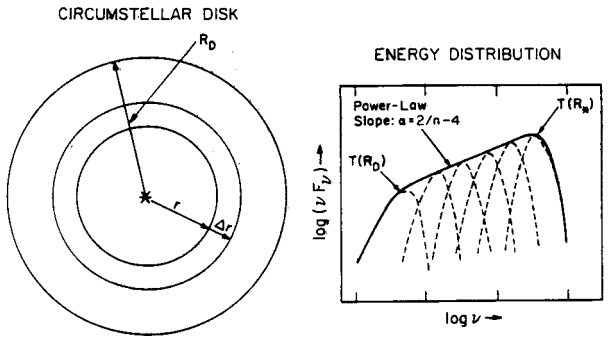

Figure 3. Schematic diagram of a spatially thin, optically thick disk and its emergent (class II) spectral energy distribution, which is composed of a superposition of black-body functions.

radiated in each annulus is given by:

$$L_\nu \, \mathrm{d}\nu = 2\pi R \, \mathrm{d}R \, \sigma T(R)^4 \sim R^{2-3n} \, \mathrm{d}\nu \sim \nu^{3-(2/n)}.$$

Therefore, if the temperature gradient in the disk is characterized by a radial power law, the emergent spectrum will also be characterized by a power-law slope in frequency or wavelength. In an SED, $\nu L_\nu \sim \nu^{4-(2/n)}$ or $\alpha = (2/n) - 4$ where α is the slope of the SED when plotted as a function of $\log \lambda$.

Thus the power-law shape of the infrared portion of class II SEDs strongly suggests that the infrared excess arises in an optically thick circumstellar disk. The slope of the SED is directly related to the temperature gradient in the disk. The slopes of class II SEDs longward of 2 μm wavelength are observed to have values in the range between -0.7 and -1.3, corresponding to a range in n, the index of the disk temperature gradient, of 0.6–0.75. A viscous accretion disk is predicted to produce a temperature gradient characterized by $n = 0.75$ which corresponds to $\alpha = -1.33$. This also turns out to be the same temperature gradient and spectral slope predicted for a flat purely passive disk which derives its luminosity from the reprocessing and re-radiation of light it has absorbed from the central star. The majority of class II sources have shallower slopes (typically $\alpha \approx -0.7$) which suggests that they are surrounded by flared (passive) disks.

The excellent agreement between the predictions of disk models and observations suggests that the most likely interpretation of the nature of class II sources is that they represent young stars surrounded by circumstellar disks. They differ from class I objects in that they lack large, massive (infalling) envelopes of gas and dust (see DUSTY CIRCUMSTELLAR DISKS). However, it is interesting to note that the infrared to millimeter excess emission from class II sources is sufficiently large that, if the emitting material were spherically distributed and not confined to a highly flattened structure, such as a disk, the star would suffer significantly more extinction than is observed. Indeed, disk masses derived from detection of optically thin

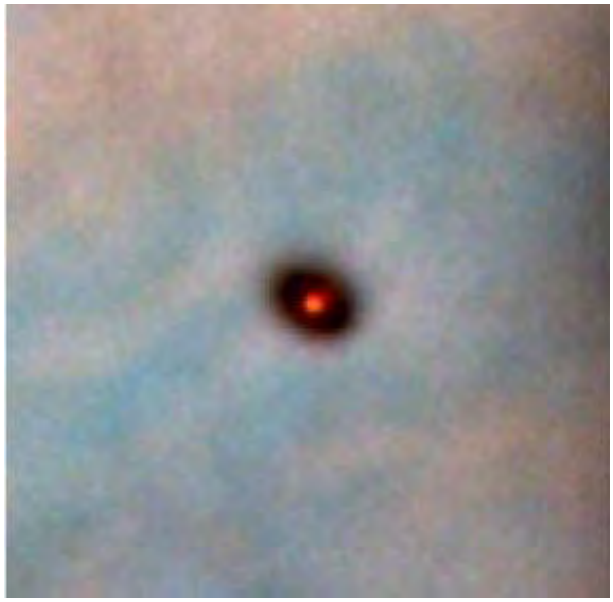

Figure 4. Resolved HST image of a circumstellar disk observed in silhoutte aganist the Orion Nebula. (Courtesy of the Space Telescope Science Institute.)

continuum millimeter-wave emission range between 0.01–0.1 solar masses. Compelling evidence confirming the disk interpretation of class II SEDs has been provided by resolved images of YSO disks obtained by interferometric observations at millimeter wavelengths and dramatic optical images by the Hubble Space Telescope (see figure 4).

Class II sources can be observed at optical as well as infrared wavelengths. Therefore, considerably more is known about the nature of these objects than is known about class I or class 0 sources. When observed optically class II sources typically exhibit the characteristics of classical T TAURI STARS (CTTS). Conversely, most all CTTS stars possess class II SEDs. Classical T Tauri stars are low-mass, pre-main sequence, emission-line variable stars. In addition to excess infrared continuum emission, these stars also exhibit excess emission at ultraviolet wavelengths. The optical spectra of CTTS contain hydrogen emission lines and frequently various forbidden emission lines as well. The forbidden lines are believed to arise in stellar winds originating near the surface of the star. Typically these lines are observed to be blueshifted and the absence of redshifted emission is interpreted as strong supporting evidence for the presence of an occulting disk close to the stellar surface. The origin of the Balmer emission lines is more mysterious. Analysis of these lines provides evidence for both mass loss and mass loss in these objects. However, both the mass loss and ultraviolet excess are believed to be consequences of disk accretion onto the stars. The accretion rates are typically $\sim 10^{-8}$ $M_\odot$ yr^{-1} and, though significant, are relatively low compared to the typical infall rates encountered in

protostellar evolution.

Because they are visible, CTTS can be placed on the HR diagram, and they are found to lie between the birthline and the main sequence, consistent with theoretical expectations for pre-main sequence stars. The existence of CTTS near the birthline indicates that circumstellar disks form in the protostellar phase of evolution as part of the collapse and infall process prior to PMS evolution. When their positions are compared to theoretical PMS calculations (which predict trajectories or tracks of early stellar evolution on the HR diagram) one derives ages for CTTS usually between 10^6 and 4×10^6 years, although such comparisons are hampered by the fact that most existing calculations assume diskless stars and the process of accretion of disk material can have an effect on the evolution of a star's luminosity and temperature. Class II sources are relatively common in star formation regions where they typically outnumber class I sources by more than 10 to 1.

Knowledge of the duration of the class II or CTTS phase of evolution has interesting implications for the formation of planetary systems. Analogy with the solar system suggests that planets are likely formed in circumstellar disks. The duration of the class II phase of evolution therefore sets limits on the duration of planet building around a young star. The typical lifetime of a class II source deduced from observations of young clusters is about 3–4 million years. The initial stages of planet formation must occur during this interval. However, it is important to note here that the duration of the class II phase may vary significantly between stars of differing mass and even stars of similar mass formed in different environments or with different initial conditions. For example, in the Trapezium cluster in Orion, ionizing radiation from a massive O star appears to be evaporating the circumstellar disks of other nearby cluster stars. This results in abbreviated disk lifetimes ($\leq 10^6$ yr) for those stars and may present difficulties for planet formation in their short-lived disks.

Class III SEDs typically peak at visible and infrared wavelengths for low mass stars and decrease longward of two microns more steeply than class II sources. Since their shapes are more or less similar to single-temperature black bodies, the energy distributions of class III sources are readily interpreted as arising from extincted or unextincted photospheres of young stars. By definition these stars display no infrared excess. However, their light still could be substantially extinguished by foreground dust.

Class III sources can be readily placed on the HR diagram. Class III sources are found to lie above the main sequence and can be thought of as 'classical' pre-main sequence stars in the sense that their positions on the HR diagram can be unambigously compared to predictions of theoretical PMS tracks (for diskless stars). Comparison with such theoretical tracks shows that the ages of class III sources range from roughly 10^6 yr to more than 10^7 yr. Although most class III sources have ages $>5 \times 10^6$ yr, and are likely candidates for post T Tauri stars (PTTS), a significant number have ages which overlap with those of classical T Tauri Stars (CTTS). This indicates that many stars may evolve through the CTTS or class II phase of evolution very rapidly ($<10^6$ yr). Class III sources are relatively strong (but variable) x-ray sources and can be identified in x-ray surveys. In the Taurus region such observations suggest that the population of class III sources is at least comparable in size to that of class II sources. Older class III objects are also found to extend well beyond the boundaries of star formation regions in x-ray surveys. Class III sources typically produce little or no Hα line emission. All class III sources are therefore weak-lined T Tauri stars (WTTS). (Optical astronomers classify PMS stars with Hα equivalent widths less than 10 Å as WTTS and PMS stars with Hα equivalent widths greater than 10 Å as CTTS.)

Bipolar jets, outflows and protostellar evolution

Although the SED classes discussed above correspond to distinct physical classes of YSOs, the variation in the shapes of the energy distributions from class 0 to III is quasi-continuous. It corresponds to a sequence of the gradual dissipation of circumstellar gas and dust around newly formed stars and represents a continuous sequence of evolution from protostar to main sequence star. To evolve from class 0 to I to II requires the removal of the circumstellar material contained in a protostellar envelope. In principle, the clearing of circumstellar gas and dust could be accomplished by accreting all the surrounding material onto the star itself. However, this possiblility conflicts with the observation that star formation is an inefficient process. The cores which form stars contain considerably more mass than the stars which they produce. Thus, the removal of circumstellar gas and dust would appear to require some active physical agent. This agent is most likely the energetic bipolar outflow that is ignited early in the protostellar phase of evolution (see figure 5).

An unanticipated phenomenon of fundamental importance for star formation, bipolar molecular outflows were only discovered by millimeter wave observations in the late 1970s and early 1980s. Bipolar outflows are very energetic flows of cold molecular gas generally consisting of two spatially separate lobes moving diametrically away from an embedded YSO at hypersonic velocities. These outflows are very massive, often containing considerably more mass than the central YSO which drives them. This indicates that the molecular outflows primarily consist of swept-up material and not ejecta from the embedded driving star itself. Bipolar outflows are the manifestation of an underlying primary wind generated by the embryonic protostellar core.

Other manifestations of this primary driving wind include Herbig–Haro objects, circumstellar jets and water masers. Herbig–Haro objects are clumps of shock-excited gas created by the collision of the primary wind with dense ambient cloud material. Herbig–Haro

Figure 5. HST image of a bipolar outflow at optical wavelengths. The two blobs of emission are the Herbig–Haro objects 1 and 2. The visible emission originates in shock-excited gas interacting with a hidden high-velocity bipolar wind generated by an invisible class I protostar located in the dark cloud core between the two lobes. (Courtesy of the Space Telescope Science Institute.)

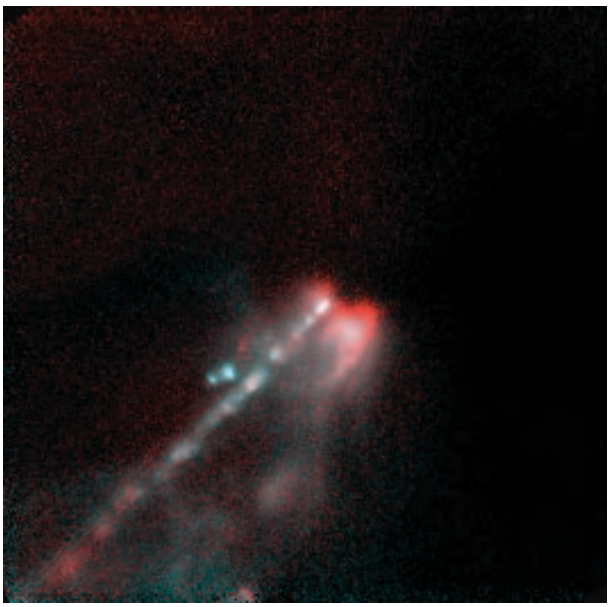

Figure 6. Infrared HST (NICMOS) image of one of the circumstellar jets that drives the bipolar Herbig–Haro 1–2 outflow system shown in figure 5. The class I protostellar source which produces the jet is so deeply buried that it is not visible even in this deep infrared image. It is located near the upper right corner of the image in a region devoid of emission. However, light from the protostar is visible in this image. The extended infrared reflection nebula, which surrounds the jet, is produced by light from the obscured protostar which has been scattered into our line of sight by dust in the cavity created by the outflow. (Image courtesy of John Bally and Bo Reipurth and the Space Telescope Science Institute.)

objects emit primarily emission-lines and are brightest at optical and infrared wavelengths (see HERBIG–HARO OBJECTS AND EXCITING STARS). They are known to be interacting with very fast ($v_{\rm wind} > 100$ km s^{-1}) winds and often display proper motions of similar magnitude. Similar to molecular outflows, Herbig–Haro objects often exhibit bipolar morphologies and can extend over distances (i.e. $\approx$1 pc) comparable to the largest molecular outflows. Water maser sources arise in very small but dense regions where the conditions are such that certain microwave transitions of H_2O become nonlinearly amplified by stimulated emission and as a result extremely bright. Like Herbig–Haro objects, maser sources often display significant proper motions and likely represent material interacting with and swept up by the fast primary wind.

Very close to the surface of the protostellar object, the primary wind is most often manifest by a highly collimated, circumstellar jet (see figure 6). These jets contain sufficiently hot and ionized gas to emit at optical as well as centimeter wavelengths. Although such jets appear to originate very close ($\leq$50 AU) to the protostellar core, they can also extend to large distances from the central object. Such jets are frequently observed to terminate at Herbig–Haro objects which have the shapes of extended bow shocks. Such jet–bow shock systems often exhibit bipolar morphologies similar to bipolar outflows.

Bipolar outflows are individually energetic enough to disrupt a protostellar envelope as well as an entire dense cloud core. Indeed, the masses of some outflows (e.g. MonR2) are known to be comparable to those of the cloud cores in which they originate. Bipolar outflows are therefore capable of driving the evolution of a protostar from the embedded class 0 to the revealed class II phase. Moreover, in the process of removing surrounding circumstellar material, outflows play a significant role in determing the final mass of the central star. Exactly how this mass is determined and how the initial spectrum of stellar mass (i.e. the initial mass function or IMF) originates are open questions.

The high frequency of association with embedded sources indicates that such outflows are ignited very early in protostellar evolution and have a duration comparable to the lifetimes of the protostars that drive them. This raises the apparent paradox that protostars are simultaneously sources of both infall and outflow. The resolution to this paradox, as mentioned earlier, is that outflows must be accretion driven.

Bipolar outflows are almost always associated with embedded class 0 and I sources and very rarely with class II or III stars. There is some evidence to indicate that outflows decline in energy as a source evolves from a class 0 to class I stage. Without massive infalling envelopes, accretion rates in class II sources are not robust enough to continue to drive energetic outflows. To evolve from a class II to III stage likely results from the accretion of the remaining circumstellar disk material onto the star.

Disk accretion in the class II (or even class 0 and I) stages may not be steady. There is a subset of YSOs, called FU Ori stars, which appear to be characterized by non-steady accretion histories. These stars display either episodic brightness variations of large amplitude or spectral signatures associated with unusually high disk accretion rates. The prototype of this class, FU Orionis, experienced an intense outburst in which its luminosity increased by a factor of 100 in less than one year. Prior to this outbust, FU Ori appeared to be a typical CTTS. The accretion rate necessary to power its outburst luminosity is $\sim 10^{-4}\ M_{\odot}\ \mathrm{yr}^{-1}$ which is significantly in excess of the accretion rates characteristic of protostellar objects ($2–6 \times 10^{-6}\ M_{\odot}\ \mathrm{yr}^{-1}$) and class II sources ($\sim 10^{-8}\ M_{\odot}\ \mathrm{yr}^{-1}$). FU Ori outbursts are believed to be short lived ($\sim$100 yr) and for most sources not as energetic as that experienced by FU Ori itself. However, such bursts of accretion may occur frequently during the early evolution of a YSO and a star could accrete a significant portion of its final mass in such episodes.

Young stellar objects of high mass

Despite their somewhat different history of formation and early development, high mass ($M_* > 2\ M_{\odot}$) stars can sometimes display characteristics similar to low mass YSOs. This is particularly true for intermediate mass stars ($2 \leq M_* \leq 10\ M\odot$) whose formation and early evolution is most similar to that of low-mass YSOs. Intermediate mass pre-main sequence stars are known as Herbig AeBe (HAEBE) stars. More massive analogs of CTTS, the HAEBE stars are emission-line stars which typically display class II SEDs and therefore possess circumstellar disks. They range in age between $0.5–5 \times 10^6$ yr, similar to CTTS. Luminous ($L > 10^2\ L\odot$) class I sources are the likely precursors to HAEBE stars.

For more massive stars (i.e. $M_* > 8\ M_{\odot}$) there is no pre-main sequence phase. When a protostar grows to a mass in excess of about 10 $M_{\odot}$, it begins to emit copious amounts of ultraviolet radiation. This results in the dissociation and ionization of all the hydrogen in the immediate circumstellar vicinity of the protostellar core. A small, dense region of hot (10^4 K) ionized gas, known as an ultra-compact H II REGION, is then produced. Because the pressure in the ionized gas can be as much as three orders of magnitude higher than that in the surrounding material, the H II region expands rapidly, at the speed of sound ($10\,\mathrm{km\,s}^{-1}$) characterizing the ionized gas. It quickly evolves into a compact H II region and then ultimately a fullblown H II region. In the process the protostar quickly evaporates and disrupts its circumstellar disk and infalling envelope and perhaps even those of neighboring stars as well. The lifetime of such massive protostars is likley very short ($<10^4$–10^5 yr). Yet, high-mass protostars also manage to produce bipolar outflows and masers. Little more is known about the protostellar evolution of massive stars. Their brief protostellar lifetimes, coupled with the fact that massive stars are intrinsically rare, makes it extremely difficult to find and investigate examples of such protostars. Such objects can be expected to be located at very large distances from the Earth making their detailed study difficult. Moreover, massive protostars are so energetic that they significantly alter the conditions in the surrounding natal material making the processes of protostellar and early post-protostellar evolution difficult to distinguish.

Z Andromedae (Z And)

Z And is the prototypical SYMBIOTIC STAR. Discovered as a mundane M-type VARIABLE STAR with a 2 mag range in visual brightness, Z And rose to prominence in the 1920s when JOHN STANLEY PLASKETT reported a peculiar class A spectrum with strong nebular lines on spectra near maximum light. Frank Scott Hogg later noted TiO bands on Plaskett's spectra. The simultaneous presence of A-type features with the TiO bands observed in much cooler M-type stars led Hogg to speculate that Z And and a handful of similar 'stars with combination spectra' might be a new type of (binary) stellar system. Roughly a dozen of these systems were known in the 1940s, when PAUL MERRILL coined the term symbiotic star for the class.

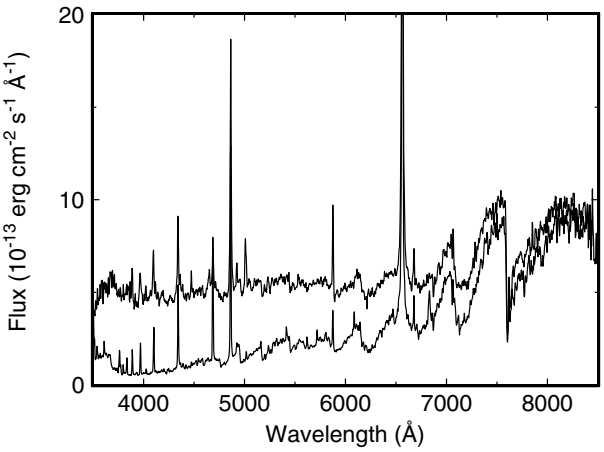

Figure 1. Spectra of Z And in quiescence (lower curve) and outburst (upper curve). The red end of the spectrum is dominated by TiO absorption bands and a strong Hα emission line. The blue continuum is weak in quiesence but rises by a factor of 3–10 in outburst. Several strong emission lines fade in outburst, while other increase in intensity.

Basic properties

As in all symbiotic stars, the behavior of Z And can be divided into two states, eruption and quiescence. During quiescence, the optical spectrum resembles an M-type giant, with a strong red continuum and deep TiO absorption bands (figure 1). This continuum peaks in the near-infrared, where CO absorption bands dominate the spectrum. In addition to the M-type stellar photopshere, optical data show a weak blue continuum and intense emission lines from a variety of ionized species. The H I Balmer lines are the strongest optical lines; He II, He I and occasionally [Ne V] and [Fe VII] are also intense. The strong Balmer emission jump at 3646 Å indicates that an ionized nebula produces much of the optical continuum. This ionized nebula is roughly 10^4–10^6 times denser than the low-density gas in a typical planetary nebula or H II region. In most planetary nebulae the [O III] and [Ne III] forbidden emission lines are strong, and the He I triplet lines are usually three times more intense than the He I singlet lines. In Z And, the [O III] and [Ne III] lines are weaker than intercombination lines from C III], N III] and O III]; the He I singlet lines often rival the intensities of the triplet lines.

Ultraviolet spectra of Z And confirm the hot stellar source suggested by the prominent He I and He II emission lines. The blue continuum from this component rises steadily into the far-ultraviolet and must peak shortwards of the Lyman limit. The shape of the UV continuum suggests a temperature exceeding 10^5 K for the hot star. The emission line spectrum is particularly intense, with He II, C IV and N V as the most prominent features. These lines are fairly broad and indicate material motions in excess of $\sim$200 km s^{-1}. Despite the intense far-ultraviolet continuum and the presence of high-velocity gas, Z And is not a bright x-ray source due to strong hydrogen absorption between the binary system and the Earth. The system is a modest far-infrared and radio source due to the large amount of dust and gas in the BINARY SYSTEM.

The quiescent photometric and spectroscopic variations of Z And are remarkably complex. The main variations in the system are phased with the orbital period of 759 days. Orbital motion of the hot component has not been detected. The small amplitude of the red giant orbital motion, $\sim$7 km s^{-1}, implies masses of $\sim 2M_\odot$ for the red giant and 0.5–1.0$M_\odot$ for the hot companion if the ratio of stellar masses is 2–4 as in other symbiotics. The intensity of the blue continuum and many strong emission lines varies by factors of 2–3 every orbit. The continuum variations are usually smaller, $\sim$0.2–0.4 mag in the optical and up to 1 mag in the ultraviolet. The system is brightest when the giant lies behind the line-of-sight to the hot star and is faintest when the giant lies in front of the hot star. This behavior suggests that the RED GIANT occults the emission line region. The giant does not eclipse the hot star itself; variations in the bright ultraviolet continuum and the polarization of several emission lines indicate an orbital inclination of $\sim 45^\circ$. This inclination is much smaller than the 70° inclination needed for eclipses of the hot star.

Z And also varies on extremely short time scales. Some emission lines, notably O III λ3444, vary markedly from one night to the next, while other lines appear constant. Some emission lines, such as H I and He I, have velocity fluctuations that are several times larger than the orbital motion of 7 km s^{-1}, but these have not been investigated in much detail.

In addition to these quiescent variations, Z And undergoes occasional outbursts. Figure 2 shows a complete light curve for the system that includes all known major outbursts. Most outbursts last $\sim$7 years, and begin with a slow increase in brightness, $V \sim 10.5$–11.0 to $V \sim 9.5$, accompanied by a periodic 0.5–1.0 mag oscillation. This phase is followed by a more rapid rise to visual maximum, $V \sim 8.5$–9.5, where the optical colors decrease and the UV colors increase. Visual maximum is followed by a slow decline with a continuing 0.5–1.0 mag oscillation. Within this train of oscillations, the interval between

Copyright © Nature Publishing Group 2001

and Institute of Physics Publishing 2001
Dirac House, Temple Back, Bristol, BS1 6BE, UK

successive minima is 10–15% shorter than when the system is quiescent. During a complete outburst, there is exactly one more minimum present than in a corresponding time period during quiescence. This behavior is observed in at least two other symbiotic stars, CI Cyg and AX Per, and resembles the 'superhumps' observed in the SU UMa class of cataclysmic variables.

The fine details of these phenomena change from outburst to outburst, but the overall behavior is remarkably repeatable. During the rise to maximum, the high ionization emission features fade as the optical continuum brightens. Some high ionization emission lines, such as [Ne V] and [Fe VII], appear to weaken considerably during the rise in brightness, but the He II lines often remain strong throughout the eruption. At maximum light, the optical spectrum resembles an A-type or F-type supergiant. Bright H I lines with strong absorption cores are prominent, and He I emission lines may also have weak absorption features. These absorption and emission lines fade as the system declines from visual maximum. The TiO bands and high ionization emission lines reappear as the system fades and re-establish their pre-outburst levels once the optical continuum returns to normal.

The history of outburst observations at other wavelengths is shorter than at optical wavelengths. The infrared brightness of the giant remains constant, indicating that the giant does not participate in the eruption. In the ultraviolet, the continuum longwards of ∼1400 Å appears to rise in step with the visual brightness. The continuum at shorter wavelengths has not always followed the optical variations, but the data are sparse. The low-ionization emission lines track the optical variations; higher-ionization emission lines track the short-wavelength ultraviolet continuum. At longer wavelengths, the radio continuum flux declined as the optical brightness increased in the most recent eruptions. The light curve for these last two eruptions, however, does not resemble the prolonged outbursts in the 1930s, 1940s and 1950s. Observations of future outbursts will be needed to see whether or not this behavior is 'typical'.

A new feature of Z And's quiescent behavior is the discovery of a persistent 28 min oscillation in the optical continuum. The oscillation has an amplitude of 0.002–0.005 mag and is visible during quiescence and the most recent small outburst. The short period of the coherent oscillation suggests an association with the hot component. Although this variation could be due to pulsations in the hot star, a rotational period is the most likely explanation. If true, the period demonstrates that the hot component must be a WHITE DWARF instead of a main sequence star.

Finally, two of the strongest optical emission lines in Z And occur at 6830 Å and 7088 Å. These lines remained unidentified with any known atomic or molecular transition until Hans Schmid proposed an association with Raman scattering of the O VI 1032 Å and 1038 Å lines off neutral hydrogen atoms surrounding the binary. With high-quality optical spectropolarimetric observations, Schmid and colleagues confirmed this hypothesis and derived an orbital inclination of roughly 45° from the variation of polarization position angle with orbital phase. They followed up these measurements with a similar analysis of the symbiotic AG Draconis. The optical Raman lines at 6830 Å and 7088 Å are strong on the optical spectra of many symbiotic stars, which should allow the measurement of accurate orbital elements for many systems.

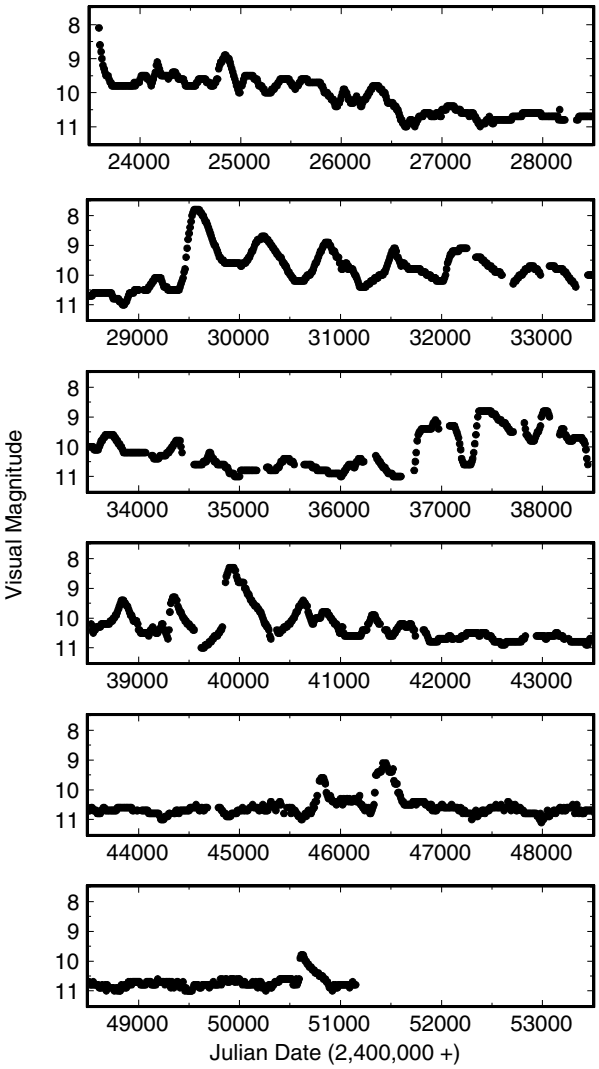

Figure 2. Optical light curve for Z And using the 10 day means of observations from the AAVSO International Database.

Interpretation

Figure 3 shows our current picture of the Z And binary system. The two stellar components are a red giant with a bolometric luminosity of roughly $3000L_{\odot}$ and a low-mass white dwarf with a luminosity of roughly $1000L_{\odot}$ for an

Copyright © Nature Publishing Group 2001

Dirac House, Temple Back, Bristol, BS1 6BE, UK

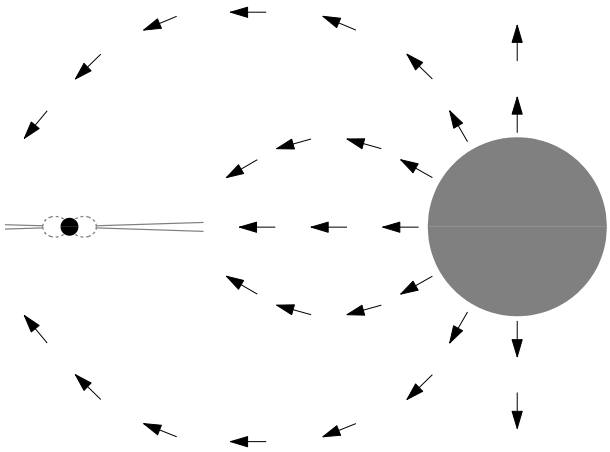

Figure 3. Schematic picture of the Z And binary. The binary consists of a red giant star (right) and a small white dwarf star (left). The red giant loses material in a stellar wind indicated by the arrows. In the orbital plane, the white dwarf deflects wind material into an accretion disk. This gas spirals inwards through the disk until it encounters the white dwarf magnetosphere. Disk material then falls onto the white dwarf along magnetic field lines, indicated as dashed lines. High-energy photons are produced by accretion through the disk and by material falling through the white dwarf's magnetosphere. These photons ionize the red giant wind. The wind heats up as it approaches the white dwarf and accretion disk. (Adapted from Kenyon (1986) and Sokoloski and Bildsten (1999).)

assumed distance of 1.5 kpc. The high luminosity of the red giant drives a low velocity stellar wind, which forms an extended envelope surrounding the binary system. Some of this material feeds an accretion disk around the white dwarf. This gas drifts inwards through the disk and falls onto the hot component. The energy generated by mass infall—either through the accretion process itself or by nuclear burning of the accreted material—produces the blue continuum; the high-energy end of this spectrum ionizes some of the surrounding nebulosity. The densest portion of the ionized nebula lies within an outflowing wind near the photosphere of the red giant. This gas has a density of at least 10^{10} cm^{-3}. The density in the gas surrounding the binary system as a whole is much lower, 10^8 cm^{-3} or less.

The simple picture is deceptive, because some of Z And's behavior remains unclear. Despite relatively good knowledge about the system geometry, the mass of the white dwarf is uncertain by a factor of two. The relative contributions of the disk and the hot white dwarf to the total luminosity are not known. The origin of some emission lines is also poorly understood. In current models, low-ionization emission lines, such as H I and He I, form close to the red giant; higher ionization lines, such as He II and C IV, form close to the hot white dwarf. The line fluxes and profiles generally fit this picture, but the radial velocities of the lines do not. This failure probably reflects our poor understanding of wind-driven mass transfer in a close binary system.

The origin of Z And's eruptions is also a mystery. In the simplest model, the outbursts of Z And and other symbiotic stars are due to thermonuclear runaways similar to those that produce classical novae. These eruptions occur when hydrogen from the accretion disk collects on the surface of the white dwarf. Nuclear reactions begin when this material reaches a critical mass. These reactions cause the white dwarf to expand in radius by a factor of 10–100, thus producing the large observed increase in optical brightness. This dramatic increase in radius occurs at roughly constant luminosity, so the temperature of the white dwarf cools from over 10^5 K to roughly 7000 K. Aside from the apparent constancy of some high ionization emission lines, much of the ultraviolet and optical spectroscopic behavior is consistent with this picture. However, the rapid recurrence time of 10–20 years is much smaller than has been achieved in any calculation of an outburst in conditions appropriate for symbiotic stars. Most calculations imply a recurrence time of 100 years or more.

Additional study is needed to unravel the nature of Z And's eruptions. Further work on repetitive thermonuclear runaways may reveal a mechanism that allows outbursts every 10–20 years. The main alternative to the thermonculear picture, disk instabilities similar to those responsible for dwarf NOVA eruptions, naturally produces such short recurrence times, but cannot explain the apparent constancy of the bolometric luminosity throughout an eruption. If future observations show that the luminosity is not constant, a disk instability might provide a better explanation for the eruptions of this prototypical symbiotic star.

Zeeman Effect

The splitting of a spectral line into two, three or more components, that occurs when the source of that line lies within a magnetic field. This phenomenon is named after the Dutch physicist, Pieter Zeeman (1865–1943), who discovered the effect in the laboratory, in 1896. The separation of the components of a line is proportional to the strength of the magnetic field and the number of components, and the polarization of the light in each component depends on the orientation of the field to the observer's line of sight. The Zeeman effect enables the strength and orientation of magnetic fields (for example, the magnetic fields in sunspots) to be measured. Where the components are too close together to be resolved into separate lines, the line appears broader than would be the case in the absence of a magnetic field (this phenomenon is called Zeeman broadening).

The Zeeman effect occurs because each of an atom's orbiting electrons has a small magnetic field (or magnetic moment). When the atom is placed in a magnetic field, the electrons can align themselves at certain discrete angles to the magnetic field (the orientations are quantized), each of which corresponds to a marginally different energy level. Consequently, each energy level of the atom is split into two or more closely spaced sub-levels, and more transitions (movements of an electron from one level to another) are then possible, each transition corresponding to a spectral line (or a component of a line).

Zeeman, Pieter (1865–1943)

Physicist, born in Zonnemaire, on the isle of Schouwen, Zeeland, Netherlands, Nobel prizewinner for physics in 1902 with HENDRIK ANTOON LORENTZ 'in recognition of the extraordinary service they rendered by their researches into the influence of magnetism upon radiation phenomena'. Became professor at Leiden University, where he discovered the splitting of spectral lines by a strong magnetic field, indicating the quantization of the spin of the electron, their negative charge, and the unexpectedly high ratio of their charge and mass (e/m). Zeeman predicted that *Zeeman splitting* should be seen in the magnetic field of the Sun, and this was completely verified by GEORGE HALE, at Mount Wilson Observatory, even to the correct interrelationship between the directions of polarization and the magnetic fields.

Zel'dovich [Zeldovich, Seldowitsch], Yakov Borisovich (1914–87)

Russian physicist, worked at the Institute of Chemical Physics in Leningrad (later in Moscow), played a significant role in the development of Soviet nuclear and thermonuclear weapons. In the 1960s he worked on astrophysics and cosmology, including the theory of black holes, the formation of galaxies and clusters, and the large-scale structure of the universe. He identified the *Sunyaev–Zel'dovich* effect of a 'shadow' in the cosmic microwave background caused by intervening electrons in clusters of galaxies. He developed astroparticle physics in the cosmological theory of the Big Bang and started to develop a quantum theory of gravity.

Zenithal Hourly Rate (ZHR)

A measure of the activity of a meteor shower that takes into account various observational factors. It is defined as the number of meteors that would be seen by a single 'ideal' observer in a cloudless, perfectly dark sky if the radiant were at the zenith. The ZHR is always greater than the observed hourly rate. It is calculated as

$$\mathrm{ZHR} = (N/t) \times R \times L \times C$$

where N is the number of shower meteors observed in time t (in hours), R is the radiant-elevation correction factor, L is the limiting-magnitude correction factor and C is the cloud correction factor. The simplest expression for R is $1/\sin\alpha$, where α is the mean elevation in degrees of the radiant over the time t; more complex formulae give slightly better results, particularly for small values of α. The next correction factor, L, is given by $r^{6.5-\mathrm{LM}}$, where r is the population index and LM the observer's limiting magnitude, 6.5 being the assumed limiting magnitude for a perfectly dark sky. Values of ZHR become unreliable when LM is worse than about 5. The population index is a measure of the magnitude distribution of a shower. Older meteor streams are depleted in smaller meteoroids and produce a lower proportion of faint meteors; their r values are higher (e.g. for the Lyrids, $r = 2.9$). Younger meteor streams yield a more even distribution of meteor magnitudes and have lower r values (e.g. $r = 2.1$ for the Quadrantids). The third correction factor is given by $C = 1/(1 - x)$, where x is the cloud cover expressed as a fraction; if x exceeds one-fifth the calculated ZHR will be unreliable. The error associated with the overall result is obtained by dividing it by $\sqrt{N}$. A similar formula (without the R term) can be applied to observed rates for sporadic meteors to give the *sporadic hourly rate* (or *corrected hourly rate*). For sporadic meteors, $r = 3.42$.

Zero Gravity

A term sometimes used to describe the state of weightlessness or free fall. Weightlessness is the sensation experienced by a body falling freely under the influence of gravity, in other words, experiencing no resistance to its acceleration. An astronaut in a spacecraft which is coasting in a gravitational field experiences no sensation of weight as both he and his surroundings are 'falling' at the same rate. Zero gravity does not imply that there is no gravity acting. A person in a freely falling lift will be accelerating at the same rate as the lift itself; therefore, there will be no relative acceleration (and therefore no force) between the floor of the lift and his feet. He feels no sensation of weight, but both he and the lift are falling in the Earth's gravitational field.

Zhang Heng [Chang Heng] (78–139)

Mathematician, astronomer and geographer, born in Nanyang, China, became chief astrologer and minister under the Emperor An'ti, corrected the calendar to bring it into line with the seasons. Invented the first seismoscope for measuring earthquakes, essentially a series of finely balanced balls that dropped and made a noise when there was a tremor. He constructed a rotating celestial globe as a model of the universe and described the 320 stars that can be named, out of the 11 520 very small stars, apparently visible to the naked eye (it must have been possible to see beyond magnitude 6.5 in China).

Zodiacal Light

A faint cone-shaped glow in the night sky stretching along the ecliptic, alternatively known as the *counterglow* or *gegenschein*. Given a dark sky and the absence of moonlight, it is visible at all times from the tropics. From temperate latitudes it is best seen about an hour and a half before sunrise in the fall or the same time after sunset in the spring, for at these times the ecliptic makes its greatest angle with the horizon. The zodiacal light is caused by sunlight scattered by interplanetary dust particles in the plane of the ecliptic.

See also: interplanetary dust.

Zond

Series of eight Soviet deep space missions. Launched 1964–1970. Zond 1 was a failed Venus flyby. Zond 2 was a failed Mars mission. Zond 3 (launched July 1965) conducted a lunar flyby. Zonds 4–8 were part of the test programme for a Soviet manned lunar mission. Zond 5 (launched September 1968) was the first spacecraft to successfully circumnavigate the Moon and return to Earth. Zond means 'probe'.

Zucchi, Niccolo (1586–1670)

Born in Parma, Italy, became a Jesuit, and in 1608, or perhaps 1616, used a lens to observe the image produced by a concave mirror, the first reflecting telescope. He described it in a book *Optica Philosophica*, in 1652. He was the first to observe the spots on Jupiter, in 1630. In about 1640, he is reported to have examined spots on Mars, as discovered by Fontana, but this must be regarded skeptically, unless his telescope was better than is believed.

Zwicky, Fritz (1898–1974)

Swiss physicist, born in Varna, Bulgaria, became professor at the California Institute of Technology. He researched galaxies and produced a comprehensive catalog of them. He had an all-inclusive approach to astronomy, which suggested that if something was physically possible then it existed somewhere in the universe—he called this 'morphological astronomy'. In 1934 he predicted the existence of neutron stars and black holes, formed by supernovae (a word he coined). His studies of the dynamics of galaxies showed the existence of dark matter decades before this was generally accepted.

ZZ Ceti Stars

ZZ Ceti is the generic name for pulsating WHITE DWARFS of type DA, which have a pure hydrogen outer layer composition. This name is equivalent to DAV (for variable DA white dwarfs) frequently used in the literature.

At the end of their evolution, medium mass stars ($M \lesssim 6$–$8\,M_\odot$) become white dwarfs. After transformation of their central hydrogen into helium on the main sequence, and of their helium into carbon and oxygen during the subsequent evolutionary phases—giant branch, horizontal branch (HB) and asymptotic giant branch (AGB)—the stars evolve towards the white dwarf stage. The white dwarfs are the naked degenerate carbon–oxygen (C–O) core surrounded by a tiny helium layer (in $\approx$ 20% of cases—the DB white dwarfs), itself surrounded by an even thinner hydrogen outer layer (in the remaining $\approx$ 80%—the DA white dwarfs). This late evolution proceeds either through the PLANETARY NEBULA phase, during which the stars expel their outer layers into the interstellar medium, or through the subdwarf sequence (sdO, sdB). The way a star becomes a white dwarf depends on whether enough hydrogen mass is left on top of the degenerate core on the HB, allowing the star to increase its luminosity from shell hydrogen burning to climb the AGB in the HERTZSPRUNG–RUSSELL DIAGRAM (HRD); if not enough hydrogen is left at this stage, the star evolves directly towards a white dwarf through the subdwarf sequence.

As no more nuclear fuel is available once the stars have reached this stage, their subsequent evolution is governed by the release of the internal thermal energy stored in their degenerate core, and of the gravitational energy available during the final contraction of the outer layers onto the degenerate core. This latter source of energy may still contribute to the stellar luminosity during the early phases of the white dwarf lifetime but rapidly becomes negligible as the stars reach their final degenerate structure.

White dwarfs constitute accordingly the graveyard of most of the stellar population in our Galaxy, and in other galaxies, except for those most massive stars which end as SUPERNOVAE. So they offer astrophysicists a way to test their current knowledge of STELLAR EVOLUTION, some phases of which are still poorly understood.

Along the two currently known channels leading to white dwarfs, the stars may become pulsationally unstable: these are the Variable Planetary Nebula Nuclei (PNNV) and the variable sdBs (also called EC14026 pulsators). Once on the white dwarf sequence, the stars cross three more instability strips as they cool down: (1) the pulsating PG1159 STARS (also called GW Vir stars), which are the nuclei of planetary nebulae after the nebulae have been diluted in the interstellar matter, at an effective temperature between 150 000 K and 80 000 K; (2) the variable DB white dwarfs (DBV) at about 25 000 K; and (3) the variable DA (ZZ Ceti stars) at about 12 000 K. Each of these groups of pulsators offers a way of studying many interesting features of their internal structure at various stages of evolution through the powerful tools of asteroseismology.

The first white dwarf pulsator discovered was the DA HL Tau 76, in 1968. But it is the one discovered next, in 1971, R548 or ZZ Ceti, which gave its name to the subsample of pulsating DA. The number of pulsating white dwarfs may seem quite small: only four PG1159, seven DB and 29 DA white dwarfs are known to pulsate at present. Not surprisingly, the ZZ Ceti form the largest group because (1) the hydrogen atmosphere white dwarfs (DA) are the most numerous and (2) the cooling time scale increases with decreasing luminosity and the ZZ Ceti define the coolest instability strip, so more stars will be found in a given range of temperature. But considering that we have been able to discover only those pulsating white dwarfs that are close enough, because of their intrinsic faintness, the population of pulsating white dwarfs may in fact constitute the largest group of VARIABLE STARS in our Galaxy.

White dwarfs have been discovered in two main ways: from surveys of PROPER MOTIONS and from surveys of objects with a blue color excess. Faint blue stars with a large proper motion have a high probability of being white dwarfs; systematic proper motion studies such as those conducted by Giclas, Luyten and the Bruce Proper Motion survey have led to the discovery of many faint blue stars later identified spectroscopically as white dwarfs. More recently, systematic surveys aimed at discovering quasar candidates among UV or blue color excess objects have also produced new white dwarfs: i.e. the Kiso, Palomar–Green, Hamburg Quasar, Edinburgh–Cape and Montreal–Cambridge–Tololo surveys. White dwarfs with appropriate colors, or atmospheric parameters, to be candidates for pulsators are subsequently observed through fast photometry techniques to search for STELLAR PULSATIONS. Efforts to search for new pulsating white dwarfs are still ongoing and new pulsators are regularly discovered, mainly among the ZZ Ceti group.

General properties of ZZ Ceti stars

ZZ Ceti stars are found in a narrow instability strip in the HRD. The hot (blue) and cool (red) edges are beginning to be well defined since 29 ZZ Ceti stars are known. However, the precise observational location of the instability strip still needs to be improved. This can be achieved partly by improving the precision in the determination of atmospheric parameters (effective temperature T_e and surface gravity $\log g$) and partly by finding more ZZ Ceti stars. The boundaries of the ZZ Ceti instability strip depend on stellar parameters like T_e and the total mass of the star, but also on less well understood physics entering into the models like the efficiency of convective transport in the envelope. Accordingly, the location of the blue edge of the ZZ Ceti has been debated for years and is still a matter of discussion. The red edge is even more poorly understood because convection becomes an ever more important conveyor of the energy

radiated by the stars as they cool across the instability strip from blue to red. At the red edge, most of the energy is transported by convection and there is as yet no satisfactory description of the interaction between the pulsations and the convective motions. Both the blue and red edges depend on the total mass of the stars, the instability strip being wider for more massive white dwarfs. The observationally determined instability strip is about 1200 K wide for the average ZZ Ceti population, whose mean mass is the same as the mean mass of white dwarfs: $0.6\,M_{\odot}$. It extends from about 12 400 K on the blue edge to about 11 200 K on the red edge. Because the instability occurs at the effective temperature for which the hydrogen Balmer lines have their maximum equivalent widths, the method for determining $T_{\rm e}$ based on fitting these lines is unfortunately not very sensitive. The method based on fitting the satellites of the strong Lα absoption observed in the UV spectra of ZZ Ceti stars at $\lambda = 1400$ Å and $\lambda = 1600$ Å is more sensitive but requires UV spectra with a high signal/noise ratio, i.e. from the Hubble Space Telescope (HST).

Within the uncertainty in the determination of the atmospheric parameters, and the detection limit of the pulsations, there are no stable stars in the ZZ Ceti instability strip. All DA white dwarfs crossing the ZZ Ceti instability strip should become pulsators. As a consequence, the properties derived for ZZ Ceti from asteroseismology are presumably applicable to all DA white dwarfs.

The pulsations observed in ZZ Ceti stars are non-radial oscillations excited by the κ–γ mechanism and by the response of the surface convection zone, both resulting from the recombination of ionized hydrogen in the stellar envelope. Theoretical models show this to happen at the $T_{\rm e}$ corresponding to the blue edge. Additional complications occur at cooler temperatures as the radiative flux and the convective flux, both perturbed by the oscillations, start interacting nonlinearly, making the theoretical modeling much more complex. Most of our present understanding of pulsating white dwarfs comes from linear pulsation theory, in which only information derived from the frequency of the oscillations is used.

Non-radial oscillations in stars manifest themselves in the form of waves of two types: (a) pressure modes (or p-modes) for which pressure is the restoring force; they are acoustic waves; and (b) gravity modes (or g-modes), for which buoyancy is the restoring force. In ZZ Ceti stars, p-modes would have periods of the order of 1 second or less, and the corresponding motions of the gas, mainly in the vertical direction, would have to fight the high gravity of the star, resulting in a very small amplitude. These modes, while predicted to be unstable, have never been detected. The g-modes have periods two to three orders of magnitude longer, from about 100 s to about 1200 s. The motion of the gas induced by the pulsations becomes dominantly horizontal close to the surface and the high gravity is no longer an obstacle to the propagation of the waves. g-modes propagate as waves at the surface of the stars, producing temperature fluctuations which translate into flux variations detectable by very sensitive instruments like photomultiplier photometers and, more recently, CCD photometers. They also propagate inside the stars, but they can do that only in those regions of the star where their frequency is lower than the Brunt-Väisälä frequency (N) and the Lamb frequency. N is the characteristic frequency with which a particle of gas taken away from its equilibrium position in the radiative part of the star returns to its original location through oscillations. The Lamb frequency characterizes the local sound frequency corresponding to the degree of the non-radial mode ℓ. This criterion defines cavities inside the star in which the waves can propagate.

Because of the spherical symmetry of the star, and assuming that the rotation is small enough to preserve that symmetry, the non-radial oscillations follow a geometry defined by spherical harmonics in the horizontal direction. This horizontal structure is characterized by the degree ℓ of the spherical harmonics, which may be understood as the number of lines of nodes of the gas motions on a spherical surface, and by the azimuthal number m, which is the number of those particular lines of nodes passing through the poles defined by the pulsation axis of symmetry. In the vertical direction, a given mode has a structure which is the solution of the eigenvalue problem obeying the boundary conditions at the surface and in the center of the star. The order k (or n depending on conventions adopted by various authors) is the number of nodes of the radial component of the eigenfunction. In white dwarfs, because the core is degenerate, the g-modes do not propagate deep in the interior as N tends to 0 in degenerate matter. A g-mode of frequency f is consequently reflected at the depth where f equals the local value of N. So, contrary to the case of normal stars, like the Sun and other low-mass main sequence stars, where the expected detection of g-modes would allow study of their deep internal structure, in white dwarfs the observed g-modes allow study of the structure of the outer regions lying above the degenerate core.

An interesting property of the g-modes is that, for a given degree ℓ, and for high order k, modes of successive order become regularly spaced in period: this is called the asymptotic regime and the difference in period between successive orders is the period spacing. Departures from regular spacing are induced by quasi-discontinuities in the chemical composition found in white dwarfs at the interface between the outer H and He layers, and deeper between the He and the C–O core: this is referred to as mode trapping.

Modes of same degree and order, but with different value of m (where $-\ell \leq m \leq \ell$) have the same frequency in a non-rotating, non-magnetic star (mode degeneracy). Rotation breaks the degeneracy, and in the limit of slow rotation (rotation period long compared to the pulsation periods) a mode of degree ℓ is split into 2ℓ+1 modes equally spaced in frequency. From the frequency separation between the components of such multiplets, it is possible to derive the rotational period of the star. Detecting triplet

or quintuplets also allows an independent check of their identification as $\ell = 1$ or $\ell = 2$ modes. Similarly, the magnetic field breaks the degeneracy, each mode of degree ℓ being split into $\ell + 1$ components, the frequency shift being proportional to B^2.

While theoretical calculations predict a large number of non-radial modes to be unstable in ZZ Ceti stars, only a small number are generally observed. The first reason is trivial: because we see the star as a point source, only large-scale perturbations of the stellar surface can be detected, i.e. small ℓ values ($\ell \leq 3$) because of geometrical averaging. Another reason is that most of the ZZ Ceti show amplitude variations. Some modes are not found when their amplitude is below the detection limit. In most cases, many observational campaigns are necessary to recover a more complete frequency spectrum. But even then, the most complete frequency spectrum is far from the expected large number of non-radial modes that can be produced by the combination of various ℓ, k and m. A very efficient selection mechanism must be invoked. The first selection mechanism that has been invoked is mode trapping: in compositionally stratified white dwarfs, it has been shown that those particular modes which have a node of their eigenfunction close to the composition interfaces have minimum pulsation kinetic energy. As a consequence they have smaller growth rates. Their amplitudes grow linearly until they saturate the energy available to the pulsations. This simple explanation is rather unsatisfactory since, as the amplitudes of the modes grow, nonlinear effects couple modes and the energy stored in the trapped modes can go back and forth in other modes, stable or unstable. But this could still act as an efficient selection mechanism. Another selection mechanism implies coupling between the pulsations and convection. Pioneering works show that convection may damp very efficiently the pulsations in large frequency domains. But the predicted instability strip in this case does not fit with the observational one.

With the increasing number of known ZZ Ceti stars, it becomes possible to determine some global properties. A clear relation between pulsation periods and T_e emerges: pulsation periods increase as T_e decreases across the instability strip. This is a consequence of the fact that the unstable g-modes should have periods comparable to or longer than the thermal time scale at the bottom of the convection zone. As the ZZ Ceti cool from the blue to the red edge of the instability strip, the outer convection zone induced by hydrogen recombination becomes deeper and the thermal time scale at the bottom increases. There is also a clear tendency for ZZ Ceti of longer periods to have larger amplitude, except close to the red edge where amplitudes fall abruptly to small values. This shows that the pulsation excitation mechanism stops being efficient at a given T_e (for a given total mass) and this defines the red edge.

Asteroseismology of ZZ Ceti stars: internal structure and evolution

The comparison of the observed frequencies with theoretical calculations based on the linear theory of NON-RADIAL STELLAR PULSATIONS allows one in principle to derive many basic parameters about the structure of the STELLAR INTERIOR and the evolution of ZZ Ceti stars. A necessary requirement, however, is to be able to unambiguously identify the pulsation modes. In the case of multiperiodic stars this is not a trivial task. The aliases introduced in the frequency spectrum by gaps in the data, unavoidable *a fortiori* in single-site observations, have encouraged the development of international ground-based networks. The Whole Earth Telescope (WET), operating since 1988, has been quite successful in the asteroseismology of PG1159 stars and the DBV. For ZZ Ceti stars, which have much fewer modes, the safe identification of the pulsation modes requires additional constraints. Such constraints may be provided by time-resolved spectroscopy, using the capability of the HST to get UV spectra, or of the Very Large Telescope. The wavelength-dependent variations of the ZZ Ceti spectrum induced by the temperature changes during the pulsation cycle have different observational signatures according to the degree ℓ of the mode, because of the different limb darkening effects on the stellar surface averaging. The simultaneous combination of ground-based fast photometry and time-resolved spectroscopy seems a promising avenue for the future of the asteroseimology of ZZ Ceti stars.

From the period spacing, one can in principle deduce the total mass. But this requires that enough modes can be identified, which is not the case for most ZZ Ceti. Additional constraints from spectroscopy are necessary to get T_e and $\log g$. When PARALLAXES are available, the radius and the mass may be derived and comparison of calculated g-modes in white dwarf models may solve the ambiguity in the identification of the degree ℓ of the observed modes.

The departure from regular period spacing predicted by mode trapping could also be used in principle to derive the mass of the outer hydrogen layer. But for the same reason that it precludes unambiguous ℓ identification, the small number of observed modes makes mode trapping very difficult, and often impossible, to detect. The mass of hydrogen is then derived from best fits with stellar models, but the solution is generally not unique. Determining the mass of the hydrogen layer left on top of the degenerate C–O core is one of the main issues in white dwarf astrophysics today because it is the main uncertainty in the white dwarf models used in other calculations: i.e. cooling time scale and calibration of the white dwarf luminosity function, effect of crystallization etc.

Rotational splitting has been measured in some ZZ Ceti. The resulting rotation periods, found in the range of a few hours to more than one day, are an indication that most, but not all, of the angular momentum is lost during stellar evolution. The exact physical mechanisms are not completely understood, but from asteroseismology of ZZ Ceti and other white dwarfs we know the final state.

Only upper limits to the magnetic fields in pulsating ZZ Ceti have been derived. No ZZ Ceti is known with a magnetic field greater than a few kG. None of the known strongly magnetic white dwarfs has been found to pulsate.

In spite of the fact that the ZZ Ceti have typical cooling times of the order of 10^9 years, the great stability of their pulsation frequencies should allow us to measure the effect of evolution on the pulsation modes. The cooling time scale depends mainly on the total mass of the degenerate quasi-isothermal core and its chemical composition. As the star cools, the internal structure changes, and the spectrum of the eigenmodes changes accordingly. A few ZZ Ceti stars are regularly observed in a follow-up program to ultimately measure the rate of period changes induced by their evolution ($\dot{P}$). Measuring $\dot{P}$ would be a unique check that the theory of stellar evolution correctly predicts the composition of the white dwarf core. The best case to date is G117-B15A, for which one has only an upper limit for $\dot{P} = 2.8 \pm 1.7 \times 10^{-15}\,\mathrm{s\,s^{-1}}$. This is consistent with the core being a C–O mixture.

In addition to the poorly determined hydrogen envelope mass in ZZ Ceti, the other major uncertainty in the calculation of the cooling sequence is the role of the crystallization phase. The release of the latent heat of crystallization slows the cooling. This is an important effect when determining the age of the oldest and coolest white dwarfs in the solar neighborhood, which in turn may be used to determine the age of the galactic disk. The predicted effect of crystallization has never been confronted to observational tests. Massive DA white dwarfs should be in the crystallization phase while crossing the ZZ Ceti instability strip. Most DA have the same mass of $0.6\,M_\odot$ and are predicted to crystallize at a T_e lower than the red edge of the ZZ Ceti instability strip. The only exception is BPM37093, which has a mass of $1.1\,M_\odot$ and is currently the only massive ZZ Ceti on which testing the efficiency of the crystallization may be undertaken. Unfortunately, the effect of crystallization on the oscillation frequency spectrum is small and the present uncertainty on the hydrogen mass layer hides its signature.

Progress on both the theoretical side of non-radial pulsations and the observations of ZZ Ceti stars should allow us in the near future to use the calibrated cooling sequence of white dwarfs to get an independent determination of the age of the galactic disk, of globular clusters etc, and to better understand the evolution of the stars whose lives end as white dwarfs.

Bibliography

The essential reference book for understanding the theory of non-radial pulsations in stars is:

Unno W, Osaki Y, Ando H, Saio H and Shibahashi H 1989 *Nonradial Oscillations of Stars* (Tokyo: University of Tokyo Press)

A recent IAU Symposium dedicated to helio-asteroseismology contains a review on pulsating white dwarfs in general:

Provost J and Schmider F-X (ed) 1997 *Sounding Solar and Stellar Interiors, IAU Symposium 181* (Dordrecht: Kluwer Academic)

The more recent European Workshops on White Dwarfs contain many contributions concerning ZZ Ceti stars; these are published in:

Koester D and Werner K 1994 *White Dwarfs, Springer Lecture Notes in Physics* (Berlin: Springer)

Isern J, Hernanz M and Garcia-Berro E 1997 *White Dwarfs* (Dordrecht: Kluwer Academic)
